1858 FORESTS AND STREAM FLOW.

By W. G. Hoyt and H. C. Troxell 1

Discussion :

By C. G. Bates 31
J. E. Willoughby 36
A. L. Sonderegger 37
J. C. Stevens 40
Harry F. Blaney 42
Daniel W. Mead 46
Ralph R. Randell 56
H. K. Barrows 57
Donald M. Baker 58
Ralph A. Smead 61
George H. Cecil 63
C. W. Sopp 66
W. P. Rowe 68
W. C. Lowdermilk 69
Rhodes E. Rule 75
Robert E. Kennedy 78
Herman Stabler 80
H. S. Gilman 86
Charles H. Lee 89
W. G. Hoyt and H. C. Troxell 94

1859 TESTS OF RIVETED AND WELDED STEEL COLUMNS.

By Willis A. Slater and M. O. Fuller 112

Discussion :

By Raymond J. Roark 143
Lyndon F. Kirkley 148
R. A. Caughey 149
E. G. Walker 151
M. Holt and R. G. Sturm 152
M. O. Fuller 153

1860 THE MARTINEZ-BENICIA BRIDGE.

By W. H. Kirkbride 154

Discussion :

By N. F. Helmers 176
E. J. Schneider 178
M. F. Clements 180
Jacob Feld 185
W. H. Kirkbride 188

No. PAGE

1861 PRE-QUALIFICATION OF CONTRACTORS.
By C. J. Tilden 190
Discussion:
By Edward W. Bush 194
A. B. Edwards 197
Samuel T. Carpenter 198
Leon F. Peck 198
C. L. Hall 199
A. R. Losh 201
E. G. Walker 202
C. J. Tilden 203

1862 TESTS FOR HYDRAULIC-FILL DAMS.
By Harry H. Hatch 206
Discussion:
By Charles H. Paul 248
Joel D. Justin 251
Jeptha A. Wade 253
Stanley M. Dore 257
D. P. Krynine 260
M. M. O'Shaughnessy 263
Joel B. Cox 263
William P. Creager 277
Harry H. Hatch 278

1863 FOUNDATION TREATMENT AT RODRIGUEZ DAM.
By Charles P. Williams 295
Discussion:
By L. A. Robb 306
Francisco Gomez-Perez 309
F. A. Noetzli 310
Charles P. Williams 311

1864 A HISTORY OF THE DEVELOPMENT OF WOODEN BRIDGES.
By Robert Fletcher and J. P. Snow 314
Discussion:
By Henry B. Seaman 355
Jasper O. Draffin 357
E. K. Morse 358
John W. Storrs 359
C. J. Hogue 359
William A. Oliver 360
Philip G. Laurson 362
Richard S. Kirby 364
Wells N. Thompson 364
Benjamin Wilder Guppy 365
Ivan E. Houk 367
William H. Baker, Jr. 368
Oren Reed 370
R. P. Davis and L. L. Jemison 371
Peter T. Landsem 377
J. K. Finch 381
A. A. Eremin 383
Aksel Andersen 384
William G. Atwood 387
H. Fugl Meyer 388
W. E. Howland 389
Harry K. Ellis 391
Nelson J. Bell 392
Robert Fletcher and J. P. Snow 394

No. PAGE

1865 **DISTRIBUTION OF SHEAR IN WELDED CONNECTIONS.**
By Henry W. Troelsch 409

Discussion :
By F. T. LLEWELLYN 417
A. S. WOODLE, JR. 420
MILTON MALE 421
WILLIAM HOVGAARD 423
CHARLES W. CHASSAING 424
F. E. FAHY 426
W. H. JAMESON 427
P. WILHELM WERNER 429
ISAMU OHNO 432
HENRY W. TROELSCH 434

1866 **WORK OF RIVETS IN RIVETED JOINTS.**
By A. Hrennikoff 437

Discussion :
By HENRY W. TROELSCH 450
HENRY B. SEAMAN 451
A. H. FINLAY 452
F. P. SHEARWOOD 452
W. P. ROOP 457
H. N. HILL AND MARSHALL HOLT 464
DONALD E. LARSON 469
A. E. R. DE JONGE 474
A. HRENNIKOFF 484

1867 **STUDY OF STILLING-BASIN DESIGN.**
By C. Stanley Maxwell 490

Discussion :
By E. W. LANE 513
C. C. INGLIS 519
F. KNAPP 520
C. STANLEY MAXWELL 521

1868 **A PROBLEM OF SOIL IN TRANSPORTATION IN THE COLORADO RIVER.**
By S. L. Rothery 524

Discussion :
By C. E. GRUNSKY 544
IVAN E. HOUK 544
H. M. ROUSE 547
WILLIAM T. COLLINGS, JR. 549
R. F. WALTER 555
HARRY F. BLANEY 560
CALVIN V. DAVIS AND DIRK A. DEDEL 561
THADDEUS MERRIMAN 564
J. C. ALLISON 565
S. L. ROTHERY 569

1869 **MODEL LAW FOR MOTION OF SALT WATER THROUGH FRESH.**
By Morrough P. O'Brien and John Cherno 576

Discussion :
By W. E. HOWLAND 595
HERBERT D. VOGEL 598
C. E. GRUNSKY 599
JOHN B. DRISKO 601
G. H. KEULEGAN 602
MORROUGH P. O'BRIEN AND JOHN CHERNO 606

No. PAGE

1870 WIND STRESS ANALYSIS SIMPLIFIED.
By L. E. Grinter 610

Discussion:
By FRANCIS P. WITMER 635
ELMER K. TIMBY 635
N. A. RICHARDS 637
JOHN B. LETHERBURY 638
FREDERICK MARTIN WEISS 641
RAYMOND C. REESE 643
A. FLORIS 650
ROBINS FLEMING 651
J. D. GEDO 652
H. V. SPURR 653
JOHANNES SKYTTE 656
JOHN B. WILBUR 658
L. E. GRINTER 660

1871 EVAPORATION FROM WATER SURFACES: A SYMPOSIUM 671

EVAPORATION FROM DIFFERENT TYPES OF PANS.
By Carl Rohwer 673

EVAPORATION FROM RESERVOIR SURFACES.
By Robert Follansbee 704

STANDARD EQUIPMENT FOR EVAPORATION STATIONS: FINAL REPORT OF SUB-COMMITTEE ON EVAPORATION OF THE SPECIAL COMMITTEE ON IRRIGATION HYDRAULICS 716

Discussion:
By RALPH R. RANDELL 719
C. E. GRUNSKY 720
CHARLES H. LEE 722
S. T. HARDING 722
L. STANDISH HALL 724
ADOLPHO SANTOS, JR. 730
JOHN W. PRITCHETT 732
IVAN E. HOUK 733
R. I. MEEKER 736
CARL ROHWER 736
ROBERT FOLLANSBEE 738
SUB-COMMITTEE ON EVAPORATION, SPECIAL COMMITTEE ON IRRIGATION HYDRAULICS 746

1872 DEVELOPMENTS IN REINFORCED BRICK MASONRY.
By James H. Hansen 748

Discussion:
By W. K. HATT 769
C. T. SCHWARZE 769
J. W. MCBURNEY 771
E. G. WALKER 772
JAMES H. HANSEN 775

1873 THE PLAN OF BOSTON, MASSACHUSETTS: A CAPITAL CITY.
By Arthur C. Comey 777

Discussion:
By ROBERT WHITTEN 789

No. PAGE

1874 HIGH DAMS ON PERVIOUS GLACIAL DRIFT.
By **Edward M. Burd** 792

Discussion:
By CHARLES W. SHERMAN 819
F. B. MARSH 819
M. M. O'SHAUGHNESSY 820
H. DE B. PARSONS 821
JOEL D. JUSTIN 822
A. K. POLLOCK 826
WILLIAM P. CREAGER 827
ADOLPH J. ACKERMAN 828
J. ALBERT HOLMES 830
IRVING B. CROSBY 835
HARRY H. HATCH 837
EDWARD M. BURD 838

1875 IMPROVED TYPE OF FLOW METER FOR HYDRAULIC TURBINES.
By **Ireal A. Winter** 847

Discussion:
By C. MAXWELL STANLEY 867
R. C. JOHNSON 868
E. A. DOW 869
E. B. STROWGER 870
IREAL A. WINTER 871

1876 THREE-SPAN CONTINUOUS-TRUSS RAILROAD BRIDGE, CINCINNATI, OHIO.
By **Wilson T. Ballard** 873

Discussion:
By J. E. WILLOUGHBY 895
WILSON T. BALLARD 896

1877 ACTUAL DEFLECTIONS AND TEMPERATURES IN A TRIAL-LOAD ARCH DAM.
By **A. T. Larned and W. S. Merrill** 897

Discussion:
By GEORGE JACOB DAVIS, JR. 936
D. C. HENNY 938
B. E. TORPEN 940
LARS R. JORGENSEN 941
H. B. MUCKLESTON 946
IVAN E. HOUK 947
A. V. KARPOV AND R. L. TEMPLIN 951
A. T. LARNED AND W. S. MERRILL 955

1878 WIND STRESSES BY SLOPE DEFLECTION AND CONVERGING APPROXIMATIONS.
By **John E. Goldberg** 962

Discussion:
By G. A. MANEY 976
L. E. GRINTER 977
S. S. GORMAN 979
A. FLORIS 982
JOHN E. GOLDBERG 983

No. PAGE

1879 ON THE BEHAVIOR OF SIPHONS.
By J. C. Stevens 986

Discussion:
By Ivan M. Nelidov 1006
Herbert H. Wheaton 1008
J. C. Stevens 1009

1880 USE AND CAPACITY OF CITY STREETS.
By Hawley S. Simpson 1012

Discussion:
By R. O. Thomas 1032
Sigvald Johannesson 1034
W. W. Crosby 1035
Harold M. Lewis 1036
Hawley S. Simpson 1038

1881 STABILITY OF STRAIGHT CONCRETE GRAVITY DAMS
By D. C. Henny 1041

Discussion:
By H. de B. Parsons 1062
A. A. Eremin 1063
Calvin V. Davis 1064
William P. Creager 1066
F. W. Hanna 1068
Lars R. Jorgensen 1071
I. M. Nelidov 1074
Paul Baumann 1078
Thaddeus Merriman 1080
Ivan E. Houk 1081
A. V. Karpov 1082
L. F. Harza 1085
Edward Godfrey 1087
F. Knapp 1089
S. H. Woodard 1091
A. Floris 1097
Joseph Jacobs 1098
Robert E. Glover 1102
Charles Terzaghi 1103
D. C. Henny 1110

1882 ESTIMATING THE ECONOMIC VALUE OF PROPOSED HIGHWAY EXPENDITURES.
By Thomas R. Agg 1124

Discussion:
By W. W. Crosby 1137
Roger L. Morrison 1138
Samuel B. Folk 1139
W. S. Downs 1140
George E. Martin 1143
J. T. L. McNew 1145
H. E. Phelps 1148
C. C. Wiley 1149
Thomas R. Agg 1154

No. PAGE
1883 THE SURVEYOR AND HIS LEGAL EQUIPMENT.
By A. H. Holt 1155

Discussion:
By Ray H. Skelton 1170
William Bowie 1172
R. Robinson Rowe 1174
Walter H. Dunlap 1176
Chester Mueller 1179
Clarence T. Johnston 1184
A. F. Harley 1186
Lynn Perry 1188
C. H. Eiffert 1190
Verne G. Sanders 1192
A. H. Holt 1193

1884 PHOTO-ELASTIC ANALYSIS OF STRESSES IN COMPOSITE MATERIALS.
By A. H. Beyer and A. G. Solakian 1196

Discussion:
By H. J. Gilkey 1208
Robert V. Baud 1209
A. H. Beyer and A. G. Solakian 1211

1885 DURATION CURVES.
By H. Alden Foster 1213

Discussion:
By Richard Pfaehler 1236
Edward H. Sargent 1237
C. R. Pettis 1237
W. G. Hoyt 1240
Adolpho Santos, Jr. 1243
John D. Watson 1245
Howard L. Cook 1246
C. S. Jarvis 1249
Donald H. Mattern 1251
F. Knapp 1252
Dino Tonini 1256
H. Alden Foster 1261

1886 ANALYSIS OF UNSYMMETRICAL CONCRETE ARCHES.
By Charles S. Whitney 1268

Discussion:
By David A. Molitor 1290
Charles S. Whitney 1294

1887 INTERCEPTING SEWERS AND STORM STAND-BY TANKS AT COLUMBUS, OHIO.
By John H. Gregory R. H. Simpson, Orris Bonney, and Robert A. Allton. 1295

Discussion:
By C. B. Hoover and C. D. McGuire 1331
Julian Montgomery 1332
D. T. Mitchell 1333
Robert Spurr Weston 1335
W. W. Horner 1336
Samuel A. Greeley 1339
John H. Gregory, Orris Bonney, and Robert A. Allton 1340

No. Page

1888 DEFORMATION OF STEEL REINFORCEMENT DURING AND AFTER CONSTRUCTION.
By Sergius I. Sergev 1343

Discussion:
By William Russell Davis 1363
J. R. Worcester 1364
F. E. Richart 1365
Homer M. Hadley 1366
F. N. Menefee 1368
Sergius I. Sergev 1372

1889 FINAL REPORT OF SPECIAL COMMITTEE ON IRRIGATION HYDRAULICS. 1375

1890 TRENDS IN ENGINEERING AS A PROFESSION IN THE UNITED STATES OF AMERICA: ADDRESS AT THE ANNUAL CONVENTION, VANCOUVER, B. C., CANADA, JULY 11, 1934.
By Harrison P. Eddy 1383

ERRATA

Transactions Vol. 98.

Page 195, Footnote 3, Line 3 (omitted), should read "*Roads,* February, 1931."

Page 254, Paragraph 2, Line 2, omit words "by exciting."

Page 254, Paragraph 3, Line 7, should read, "sand, to one in which the sand predominated similarly. Others had a coarse."

Page 255, Paragraph 3, Line 7, for "attained", read "obtained".

Page 256, Paragraph 1, Line 1, for "comprehensive forces", read "compressive forces".

Page 938, Lines 3, 4, and 5, should read:

"Cost of silicon steel erected $= 4 + 0.3 (4 \times 1.34 + 1) = 5.7$ cents.
"Carbon steel, 110 lb @ 5 cents = $5.50 per sq ft.
"Silicon steel, 97 lb @ 5.66 cents = $5.49 per sq ft."

PAPERS AND REPORTS OF SPECIAL COMMITTEES PUBLISHED IN PROCEEDINGS, AM. SOC. C. E. AUGUST, 1933, TO MAY, 1934, INCLUSIVE, NOT PUBLISHED IN TRANSACTIONS VOL. 99

	Number of *Proceedings.*
WATER POWER DEVELOPMENT OF THE ST. LAWRENCE RIVER. By **Daniel W. Mead**	August, 1933
WATER-BEARING MEMBERS OF ARTICULATED BUTTRESS DAMS. By **Hakan D. Birke**	September, 1933
SOME SOIL PRESSURE TESTS. By **H. de B. Parsons**	November, 1933
LINCOLN HIGHWAY FROM JERSEY CITY TO ELIZABETH, NEW JERSEY. By **Sigvald Johannesson**	November, 1933
PRACTICAL RIVER LABORATORY HYDRAULICS. By **Herbert D. Vogel**	November, 1933
FORMATION OF FLOC BY FERRIC COAGULANTS. By **Edward Bartow, A. P. Black, and Walter E. Sansbury**	December, 1933

Number of *Proceedings.*

MODIFYING THE PHYSIOGRAPHICAL BALANCE BY CONSERVATION MEASURES.
By A. L. Sonderegger .... December, 1933

MODEL OF CALDERWOOD ARCH DAM.
By A. V. Karpov and R. L. Templin .... December, 1933

WIND-BRACING IN STEEL BUILDINGS: THIRD PROGRESS REPORT OF SUB-COMMITTEE NO. 31, COMMITTEE ON STEEL, OF THE STRUCTURAL DIVISION. .... December, 1933*

AN APPROACH TO DETERMINATE STREAM FLOW.
By Merrill M. Bernard .... January, 1934

DISCHARGE FORMULA AND TABLES FOR SHARP-CRESTED SUPPRESSED WEIRS.
By C. G. Cline .... January, 1934

RENEWAL OF MITER-GATE BEARINGS, PANAMA CANAL.
By Clinton Morse .... January, 1934

LOSS OF HEAD IN ACTIVATED SLUDGE AERATION CHANNELS.
By Darwin Wadsworth Townsend .... January, 1934

WILLIOT EQUATIONS FOR STATICALLY INDETERMINATE STRUCTURES IN COMBINATION WITH MOMENT EQUATIONS IN TERMS OF ANGULAR DISPLACEMENTS.
By Charles A. Ellis .... January, 1934

RAINFALL STUDIES FOR NEW YORK, N. Y.
By S. D. Bleich .... February, 1934

FLEXIBLE "FIRST-STORY" CONSTRUCTION FOR EARTHQUAKE RESISTANCE.
By Norman B. Green .... February, 1934

INVESTIGATION OF WEB BUCKLING IN STEEL BEAMS.
By Inge Lyse and H. J. Godfrey .... February, 1934

ANALYSIS OF SHEET-PILE BULKHEADS.
By Paul Baumann .... March, 1934

A GENERALIZED DEFLECTION THEORY FOR SUSPENSION BRIDGES.
By D. B. Steinman .... March, 1934

SAND MIXTURES AND SAND MOVEMENT IN FLUVIAL MODELS.
By Hans Kramer .... April, 1934

LABORATORY TESTS OF MULTIPLE-SPAN REINFORCED CONCRETE ARCH BRIDGES.
By Wilbur M. Wilson .... April, 1934

THE RESERVOIR AS A FLOOD-CONTROL STRUCTURE.
By George R. Clemens .... May, 1934

STRESSES IN SPACE STRUCTURES.
By F. H. Constant .... May, 1934

EXPERIMENTS WITH CONCRETE IN TORSION.
By Paul Andersen .... May, 1934

WAVE PRESSURES ON SEA-WALLS AND BREAKWATERS.

FORESTS AND STREAM FLOW

By W. G. Hoyt,[1] M. Am. Soc. C. E., and H. C. Troxell,[2]
Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. C. G. Bates, J. E. Willoughby, A. L. Sonderegger, J. C. Stevens, Harry F. Blaney, Daniel W. Mead, Ralph R. Randell, H. K. Barrows, Donald M. Baker, Ralph A. Smead, George H. Cecil, C. W. Sopp, W. P. Rowe, W. C. Lowdermilk, Rhodes E. Rule, Robert E. Kennedy, Herman Stabler, H. S. Gilman, Charles H. Lee, and W. G. Hoyt and H. C. Troxell.

Synopsis

The effect on stream flow of changes in forest and brush cover on specific natural areas is described in this paper. An experiment by the United State Forest Service and the United States Weather Bureau was conducted from 1910 to 1926 on two contiguous tracts of land in Southern Colorado. Data for this study were taken from a report[3] by Messrs. C. G. Bates and A. J. Henry. Stream flow measurements by the United States Geological Survey in co-operation with the State of California and the County of Los Angeles were begun in 1916 on certain areas in California, on some of which accidental denudation by burning afforded opportunity for comparisons not heretofore published. Detailed observations were made in both these areas for several years before changes in cover were accomplished by cutting and by fire, and were continued for several years after such changes.

The effects of the change in vegetable cover on the stream flow characteristics are discussed in this paper and conclusions drawn.

Note.—Presented at the Annual Convention, Yellowstone National Park, July 6, 1932.

INTRODUCTION

In November, 1908, the late H. M. Chittenden, M. Am. Soc. C. E., then Lieutenant-Colonel, Corps of Engineers, U. S. Army, presented a paper[4] before the Society entitled "Forests and Reservoirs in Their Relation to Stream Flow, with Particular Reference to Navigable Rivers." He summarized the opinions commonly accepted at that time, to the effect that forests exert a beneficial influence on stream flow in the following ways: (1) By storing the waters from rain and melting snow in the bed of humus that develops under forest cover, preventing their rapid rush to the streams and releasing them gradually afterward, thus acting as true reservoirs in equalizing the run-off; (2) by retarding the snow melting in the spring and prolonging the run-off from that source; (3) by increasing precipitation; and, (4) by preventing erosion of the soil on steep slopes and thereby protecting watercourses, canals, reservoirs, and similar works from accumulation of silt.

Colonel Chittenden's study had a negative conclusion. He found that no material influence upon stream flow could be attributed to forests. In its final report,[5] presented January 19, 1916, the Special Committee on Floods and Flood Prevention stated that if reforestation is considered merely from a commercial standpoint, the value to the country of reproducing timber is so great that it obtains general approval, particularly of engineers, who appreciate more than any other class the disadvantages to which the country will be subjected by the destruction of its forests.

Nevertheless, according to the Special Committee, some advocates of reforestation have claimed that forest destruction has increased the height and frequency of floods and diminished the discharge during low water. The basis of those claims for reforestation has been the beneficial influence of forests in preventing floods and improving the navigability of rivers.

This was a moot question in 1916 and the Committee pointed out that even the advocates of reforestation as a means of flood control failed to give any quantitative determination of the effects of forests upon floods. It was stated that, for the engineer to utilize any agency practically, he must know that it will produce a positive effect on which he can rely and which he can measure. The data as to the effect of forestation, soil observation, and kindred methods of flood control were admittedly not susceptible of quantitative analysis at that time.

Expressing his opinion as of 1930, the late Allen Hazen,[6] M. Am. Soc. C. E., called attention to the fact that foresters have urged the importance of forests in controlling and regulating stream flow, increasing the quantities of water available for use, and preventing and reducing flood flows. Although Mr. Hazen felt that the public had generally accepted this point of view, water-works engineers, he declared, have required some proof before they could accept this popular doctrine. Furthermore, according to Mr. Hazen, real evidence of the effect of forests upon stream flow is meager and unsatisfactory, involving the solution of a difficult problem to prove conclusively one way or the other.

[6] "Flood Flows—A Study of Sequences and Magnitude," pp. 152–154, John Wiley & Sons, Inc., 1930.

He admitted that forests undoubtedly affect stream flow in many ways, but that there was no evidence that they modify major flood flows materially. Quoting:

> "There is no reason to think that clearing of land in our country and putting it under cultivation has materially increased the flood quantities over those that existed in previous centuries. Reforesting cleared and burned mountain areas at the head-waters of rivers is advantageous from many aspects, but it is not to be counted on to make a material reduction in floods in rivers flowing from them."

During the twenty years that have elapsed since Colonel Chittenden's paper was written, extensive investigations have been conducted in the Wagonwheel Gap area, in Colorado, for the express purpose of determining the actual effect of forests on stream flow. By chance, also, a forest fire in Southern California destroyed the trees and undergrowth in an area from which records of stream flow had been collected for seven years previously. Information, therefore, is available to show quantitatively the effect on stream flow brought about (*a*) by the complete deforestation of a high mountain area having an annual precipitation of about 20 in. (one-half of which occurs in the form of snow); and (*b*) by the complete denudation of a semi-arid coastal mountain region on which the annual precipitation ranges from 16 to 60 in., with little snow. Conclusive evidence of the effect of forest cover on stream flow from these two widely different areas should be, not only of considerable interest, but also of great value in formulating policies relating to forests and the conservation of water.

It is strange, but nevertheless true, that until the investigations in the Wagonwheel Gap area were completed, no observations had ever been made of the actual effect of deforestation upon stream flow, conducted on a sufficiently large scale and covering a long enough time to insure that the results obtained and the conclusions based on them would not be subject to serious doubt. The investigations near Wagonwheel Gap and in Southern California differ materially from any made heretofore. The observations were made first on the forested areas for a length of time sufficient to determine their natural characteristics; then one of the areas was deforested and one accidentally burned, and observations were continued after the change. In previous investigations, forested and partly deforested areas have been compared only after the change had taken place, and as the regimen of the areas under natural conditions is not known, there is reasonable doubt as to the proper evaluation of the differences in run-off that were observed.

SCOPE OF INVESTIGATIONS

Wagonwheel Gap, Colorado.—Investigations were conducted jointly in the Wagonwheel Gap area, in Colorado, by the United States Forest Service and the United States Weather Bureau, during the period, June 1, 1910, to October 1, 1926.[7] The greatest credit is due to the scientists of the United

[7] *Monthly Weather Review, Supplement 30,* entitled "Forest and Stream-Flow Experiment at Wagonwheel Gap, Colorado; Final Report on Completion of the Second Phase of the Experiment," by C. G. Bates, Silviculturist, U. S. Forest Service, and A. J. Henry, Meteorologist, U. S. Weather Bureau, 1928.

States Department of Agriculture who conceived the project and so successfully carried on detailed observations. The publication of the basic data affords students and investigators the fullest opportunity to make independent analyses.

With this idea in view the writers have made a study of the basic data and have endeavored to present graphically, and in tabular form, in such a way that it may be most easily visualized by engineers and water users, the change in stream flow resulting from deforestation.

Since quantitative measurements of the actual differences in run-off resulting from deforestation and denudation are now available for the first time, the writers feel that the facts should be given far greater weight than conclusions reached by inductive reasoning.

In the following discussion the data collected, both at Wagonwheel Gap and in Southern California, are analyzed to show the effect of deforestation on (1) total run-off and distribution; (2) maximum flow and date of occurrence; (3) summer flow; (4) minimum flow and date of occurrence; and (5) erosion and silt content.

As all the conditions surrounding the Wagonwheel Gap experiment are fully discussed in the report cited, only a general outline of them will be given in this paper. The areas selected (designated for convenience Area *A* and Area *B*) were two contiguous mountain drainage basins in Mineral County, Southern Colorado, in the Rio Grande drainage basin, at altitudes between 9 000 and 11 000 ft. (see Fig. 1). The forest cover in both areas

was representative of the Rocky Mountain region as a whole, and, therefore, other conditions being similar, the results may be reasonably assumed to be representative of many mountain areas throughout the West.

Geologically and topographically both tracts were as similar as it is possible for two small contiguous areas to be, and their combined area (Area *A*, 222.5 acres, and Area *B*, 200.4 acres) was so small that they were both subject to practically identical meteorological conditions. The measurements of run-off and all meteorological observations were made with the greatest possible precision, and the results obtained may be taken at their face value.

The forest cover at the beginning of the investigation was as shown in Table 1.

TABLE 1.—NATURE AND EXTENT OF FOREST COVER IN WAGONWHEEL GAP, COLORADO

Type of cover	PERCENTAGE		Type of cover	PERCENTAGE	
	Area *A*	Area *B*		Area *A*	Area *B*
Burned and not restocked (mostly spruce)	9.5	6.6	Aspen with conifers	14.4	17.1
Barren or rock slide	2.7	3.0	Douglas fir	8.8	11.4
Grass	9.4	6.1	Mainly spruce	11.9	12.0
Aspen without conifers	34.3	43.8	Bristlecone pine (open)	9.0	....
Total				100.0	100.0

During the summer of 1919 Area *B* was deforested, all tree growth being cut except in a narrow strip along the course of the stream, which was not cut until 1920. The slash from the larger green conifers and the tops and stems of the smaller evergreens and aspens were burned in 1921. After the deforestation there was a growth of grass, herbs, and aspen, and, in places, the aspen sprouts had reached heights of 3 to 6 ft. at the end of the 7-year period. In general, the grasses were reproduced on south exposures and grass and herbs on north exposures. Messrs. Bates and Henry have used the term "denudation" to describe the removal of the trees from the area. Webster defines denudation as "act of denuding; * * * the laying bare of rocks by the removal of overlying material; erosion." The writers believe that the term "deforestation" more correctly defines the change that occurred on Area *B*, because only in isolated places where slash was burned (comprising a very small percentage of the whole), was there actual destruction of soil covering. "Denudation," however, correctly describes the change that occurred in the Southern California area.

Reliable observations at Wagonwheel Gap were made for eight years in the natural state and for seven years after deforestation. (There is some doubt as to the accuracy of the run-off records prior to August, 1911, so that the complete record runs from September, 1911, to September, 1926.) This study is based necessarily on the hypothesis that during the first eight years the run-off relations and differences between the two areas were so well indicated that the results obtained can be safely used as indices of the changes in run-off resulting from complete deforestation.

Many of the pertinent annual and monthly climatological data for the two areas are given in the accompanying tables. Briefly, the mean annual temperature was about 34° Fahr., the range being from 80° Fahr. during June, July, and August, to temperatures below zero occasionally during all months from October to March. The mean annual precipitation was about 21 in., one-half of which occurred in the form of snow. The climatic conditions were very similar during both periods.

The mean annual temperature of Area *A* was 34.0° Fahr., during both periods. The mean annual temperature of Area *B* was 1.3° warmer after deforestation than before. The mean annual precipitation over Area *A* was 21.03 in. during the first period and 21.16 in. during the second period; over Area *B*, the mean annual precipitation was 21.10 and 20.83 in., respectively, during the first and second periods. The accumulated precipitation on these two areas generally agrees within 0.5%, or less than the probable error of the observations. In the accompanying tables observations of run-off are given, in inches, over the drainage basin, corresponding to the base data given in the U. S. Weather Bureau report, and, also, in second-feet per square mile.

Southern California Area.—On August 31, 1924, a forest fire started in the San Gabriel Canyon, north of Azusa, Calif. The fire spread rapidly and had soon burned over some of the drainage areas tributary to the San Gabriel River (see stipled area in Fig. 2). Among these areas were those of Fish, Rogers, and Sawpit Creeks. The fire did not reach the drainage basin of Santa Anita Creek. On each of these creeks the U. S. Geological Survey had been operating gauging stations for several years, in co-operation with the California State Engineer and Los Angeles County. Each station was equipped with a water-stage recorder mounted in a concrete house. Measurements of discharge were made with a current meter, and the records were kept and published in the usual manner.

Of the three burned areas that of Fish Creek offers the best discharge record, in that there are no diversions from the stream nor artificial regulation above the gauging station. On Rogers Creek there are two diversions above the gauging station. No record has been kept of the quantity diverted, but although the structures are relatively small, they divert the entire flow during the summer. On Sawpit Creek the City of Monrovia diverts water above the gauging station. The city has a series of tunnels in the head-waters, which is one of the main sources of the flow in the Monrovia pipe line.

For these reasons Fish Creek was selected for the study. To establish the effect of the fire on the discharge of this creek, it was necessary to determine the relation between its flow and that of Santa Anita Creek for the period prior to the fire.

The canyons of both Fish and Santa Anita Creeks are well defined by mountain divides and are separated only by the basin of Sawpit Creek. Both streams originate at altitudes greater than 4 000 ft. The east side of Mount Wilson drains into Santa Anita Creek. Monrovia Hill, a peak of 5 267 ft., separates the head-waters of the two streams, Fish Creek draining the east side and Santa Anita Creek the west. Santa Anita Canyon is fan-shaped; Fish Canyon is oblong; and the side walls of both canyons are steep and rugged. The drainage area above the gauging station on Fish Creek is

FIG. 2.—SANTA ANITA, FISH, ROGERS, AND SAWPIT CREEKS, IN THE SOUTHERN PART OF CALIFORNIA

6.5 sq. miles, and that of Santa Anita Creek, 10.5 sq. miles. The vegetative cover consisted of a heavy brush growth of sumac (*Rhus sp.*) and mountain mahogany (*Cercocarpus montanus*). Interspersed between the brush growth were much smaller plants, such as white sage (*Artemisia californica*), grass, and yucca (*Yucca radiosa*). In sheltered tracts and on the north sides of many of the numerous small tributary canyons grew small groups of oak. In the bottoms of the canyons along the streams were large numbers of sycamores and alders. The areas are in the Angeles National Forest, but they support no timber, and neither area was used for grazing. Their principal value was for recreation.

The fire in the summer of 1924 completely stripped the canyon walls of Fish Creek of all plant life and tree litter. Some of the alders and sycamores adjacent to the stream escaped burning through the efforts of the fire fighters. After the first rains in the following spring a different plant association comprising sage, wild flowers, and grasses developed, which tended to cover the soil left bare by the fire. By the fall of 1930 little evidence of the fire remained except that possibly larger areas of white sage and small plants grew in.

The gauging stations on both streams are ideally located. The station on Santa Anita Creek is in a rock gorge and the crest of small waterfalls forms the control. On Fish Creek, the control is an outcrop of bed-rock, which was smoothed up by building a small concrete dam on it. It is doubtful if any underflow passes either station. There are no diversions above either station. The stream-flow data prior to 1927 have been published by the U. S. Geological Survey,[8] and later data are taken from unpublished records in the Survey files.

The best rainfall records in this general region are those of the Mount Wilson and Santa Anita Ranger Stations. Both stations are operated and the records published by the U. S. Weather Bureau. As it was not anticipated that a study of denudation would be made in either area, detailed climatological and other records, such as those which were collected with great care and accuracy in the Wagonwheel Gap area, are lacking for this study.

No records of temperature were collected directly in the Southern California area during the first or second period of the study. At Mount Wilson, on the western divide of Santa Anita Creek, the average annual temperature during the two periods was 55.7° Fahr., and the daily temperature ranged from about 100° Fahr. in summer to less than 32° Fahr. in winter.

EFFECT OF DEFORESTATION AND DENUDATION

Annual Run-Off.—In the following tables the period of record before deforestation and denudation is designated the "first period," and the period of record after deforestation and denudation, the "second period." The precipitation given for the Wagonwheel Gap area (Table 2) is the average of Area *A* and Area *B*; that for the Southern California area is the precipitation recorded at Mount Wilson.

---

[8] *Water Supply Papers Nos. 481, 511, 531, 551, 571, 591, 611,* and *631,* U. S. Geological Survey.

In determining the effect of deforestation and denudation on these areas it was first necessary to ascertain what the run-off of Area *B* and the Fish Creek Basin would have been if conditions of vegetative cover had not been changed by deforestation or denudation. Although the two contiguous areas, *A* and *B* at Wagonwheel Gap, appeared to be alike in many respects, their run-off relations varied greatly. For example, Area *B* before deforestation had a daily run-off as low as 50% of that of Area *A* during the rising flood stages and as high as 150% during the falling stages. (See Fig. 3.) The relation varied also during the remainder of the year, depending to a considerable extent on the magnitude of the daily discharge and the season. Variations in discharge relations also occurred in the Southern California area on Fish and Santa Anita Creeks.

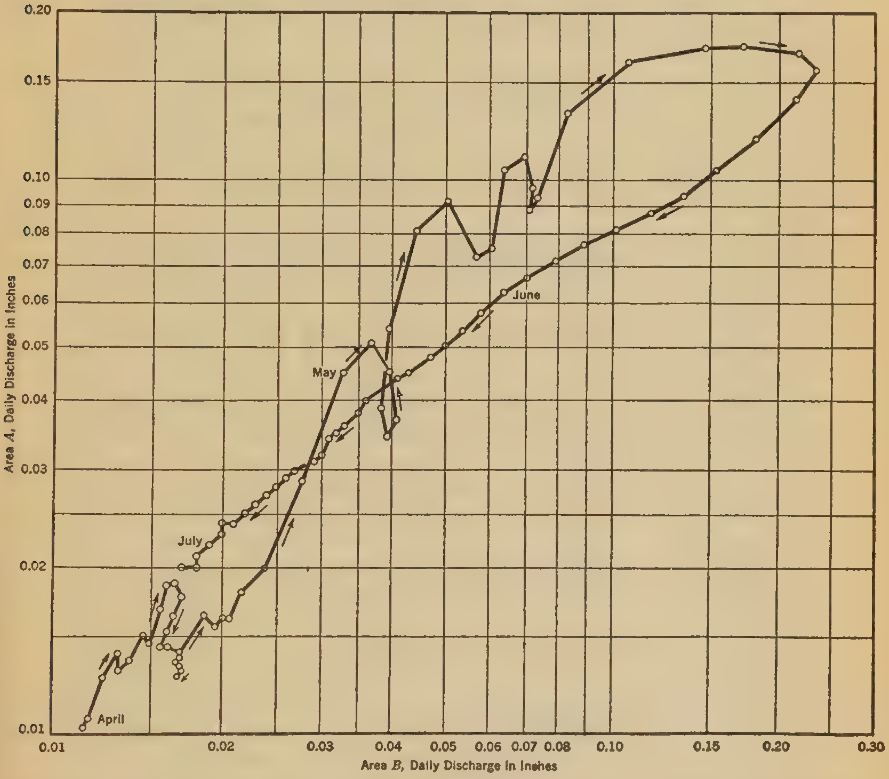

FIG. 3.—RELATION OF DAILY DISCHARGE, AREAS *A* AND *B* (WAGONWHEEL GAP), DURING RISING AND FALLING STAGES, APRIL 1 TO JULY 5, 1912

In view of these variations, the writers believed that it was desirable to compute the probable daily discharge for the period after deforestation or denudation rather than to rely on monthly figures. This permitted a much more thorough analysis of the available data.

The normal daily discharge on Area *B* was determined by comparisons established prior to deforestation, using the following methods: Beginning in October, 1919, with the falling stage on Area *B* and continuing through July,

the daily discharge on Area *A* was plotted against that of Area *B*. It was found by inspection that the relation depended to a considerable extent on the quantity of the run-off. With this in mind, the records were divided into three groups: That of 1912 and 1917, which represented the years of greatest run-off; that of 1914, 1915, 1916, and 1919, the medium years; and that of 1913 and 1918, the years of low run-off. The daily relation was plotted for each of these groups on separate sheets. A curve was then drawn averaging all the points plotted. Fig. 4 is a typical curve of relation between the run-off of Area *A* and Area *B* during the falling stages of May, June, and July in the years of greatest run-off, and Fig. 3 represents the typical daily relation during rising and falling stages. Curves were likewise drawn showing the relations that existed during August, September, October, November, December to March, and April and May.

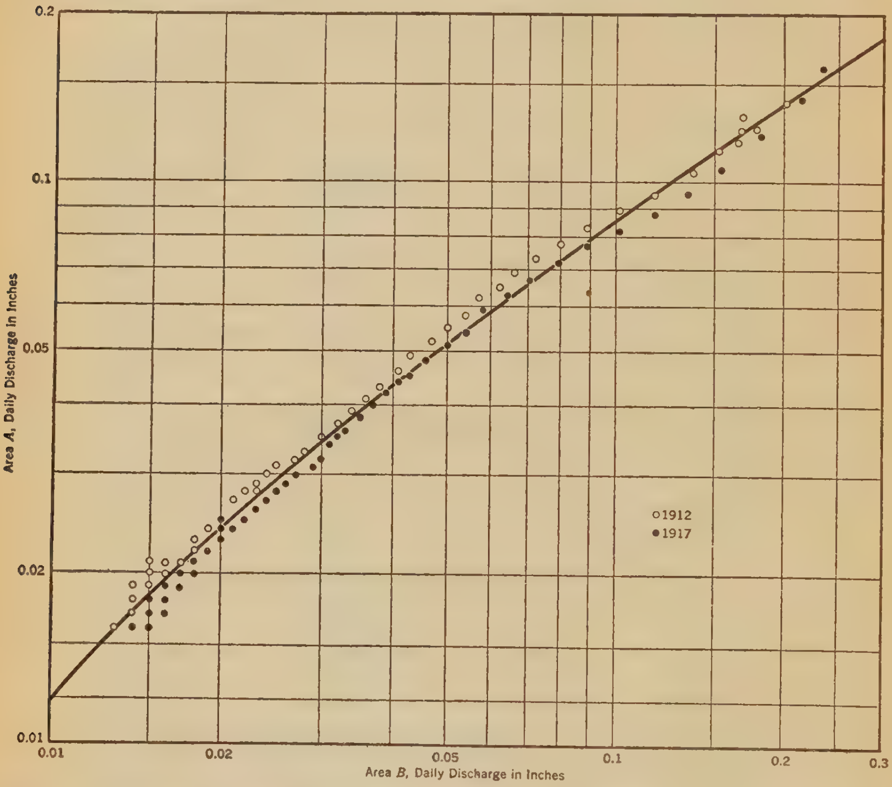

FIG. 4.—RELATION OF DAILY DISCHARGE, AREAS *A* AND *B* (WAGONWHEEL GAP), DURING FALLING STAGES, MAY TO JULY, 1912 AND 1917

The normal daily discharge in Area *B* for the period after deforestation was assumed to be the discharge obtained by applying the observed daily discharge of Area *A* to the appropriate curves, with one exception. It was noted that prior to the deforestation about three days were usually required for the change from the rising stage curve of April and May to the falling stage curve of May to July. During this three-day transition period it was necessary to make an interpolation for Area *B* based on the record from Area *A*.

For the Southern California area, curves were drawn showing the relations, prior to the fire, for January to March, April, May, June, July, August, September, and October to December. In plotting curves the observations made during 1921-22 were not used, as in that year considerable of the precipitation occurred in the form of snow, the run-off from which represented an entirely different relation. None of the seasons following denudation on Fish Creek was comparable to 1921-22.

Table 3 shows the monthly data for the second period and, in addition, the computed normal run-off, based on the relations previously described, of Area *B* and Fish Creek as it would have been had there been no change in vegetative cover. The difference between the actual and the computed normal run-off is also shown in Table 3.

The values in the last column of Table 3 show that the maximum gain on Area *B* occurred the third year after deforestation and amounted to 2.141 in., or 32.3%, and that there was a gradual decrease for the remainder of the period. On Fish Creek the maximum gain occurred the second year after the fire and amounted to 3.12 in., or 26 per cent. The gain on Fish Creek the first year after the fire was 2.47 in., or 231 per cent.

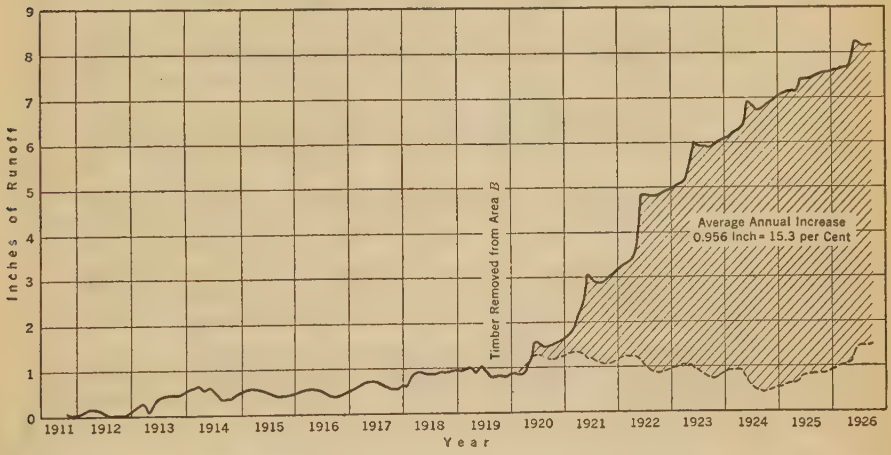

FIG. 5.—ACCUMULATED EXCESS OF RUN-OFF FOR AREA *B* OVER AREA *A*, WAGONWHEEL GAP, COLORADO

Figs. 5 and 6 show the accumulated difference in run-off of Areas *A* and *B* and of Fish and Santa Anita Creeks during the first and second periods. The cross-hatched area in Fig. 5 represents an average annual increase of 0.956 in., or 15.3%, from Area *B* during the first seven years after complete deforestation. The dashed line from 1920 to 1926 represents the normal

excess. In Fig. 6 an average annual increase of 1.55 in., or 28.7%, is indicated from Fish Creek during the first six years after complete denudation by the forest fire. On this diagram the dashed line from 1925 to 1930 represents the normal excess.

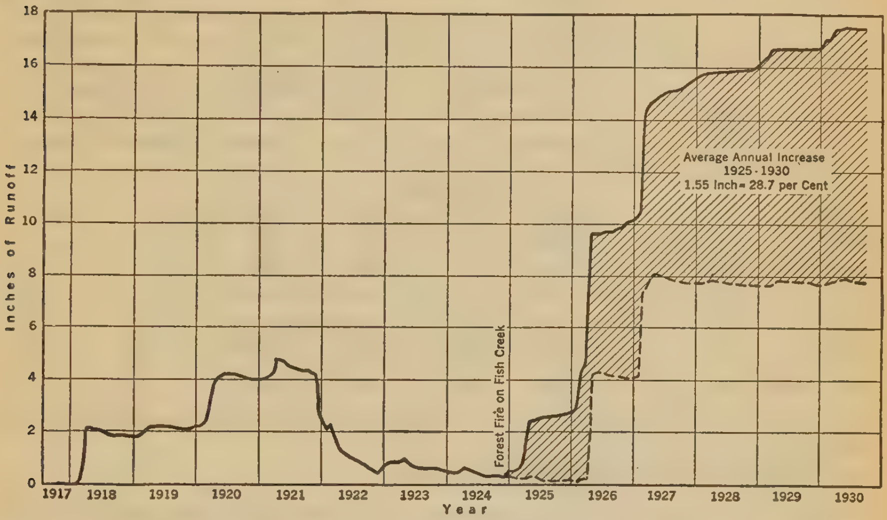

FIG. 6.—ACCUMULATED EXCESS OF RUN-OFF FOR FISH CREEK OVER SANTA ANITA CREEK IN SOUTHERN CALIFORNIA

Distribution of Increase in Annual Run-Off.—The opinion most commonly accepted is that the entire increase of run-off that follows the removal of forest cover occurs during flood periods, and that during low-water periods the run-off is decreased. It was apparent, therefore, that the increase during flood periods and also during the remainder of the year should be studied.

The floods occurring in the two areas studied are very different in type, those in the Wagonwheel Gap area being caused by melting snow as a result of high temperatures and occasional warm light rains, and those in Southern California almost entirely from rain. Stream flow in the Wagonwheel Gap area is on the increase from early April to a peak about May 20, followed by a gradual decline through the remainder of May, all of June, and the first part of July.

Table 4 shows the dates of disappearance of snow from Areas *A* and *B* during two years before and two years after deforestation; the average date of snow disappearance; and the dates of the maximum daily discharge. "Date of snow disappearance" is defined by the authors of *Weather Bureau Review, Supplement No. 30,* as "the first regular observation data on which a trace or no snow was recorded, provided that at no subsequent date a depth of 3 in. or more was recorded." Between fifteen and twenty snow scales were located in each area.

These dates are presented to show the lag between the disappearance of the snow and the peak discharge in the stream. These data and the reasonable assumption that there was no sheet run-off after the snow had gone are the basis for the statement made subsequently under the heading, "Maximum Daily Discharge," that "the gain is due to sub-surface flow as practically all the snow had melted prior to the date of maximum peak."

* Average dates of melting are published in *Weather Bureau Review, Supplement No. 30*, for only these 4 years.
† Average for the 8 years covered by the first period.
‡ Average for the 7 years covered by the second period.

Only once during the fifteen years of record in the Wagonwheel Gap area was there a flood not attributable mainly to melted snow, and this occurred during October, 1911, prior to deforestation. On the other hand, the floods in the Southern California area may occur at any time after rains, although the most usual time is between December and May. A flood in the Southern California area comes to a peak within a few hours after the rain and seldom lasts more than three days.

In this study the term, "flood period," is roughly defined as a period of major surface run-off as distinguished from the period during which the streams are fed mainly, if not entirely, from sub-surface sources. Owing to the nature of the run-off in the California area the flood periods there are well defined and usually extend over a period of a few days. The run-off during these periods is usually greater than 4 sec-ft. per sq. mile. In the Wagonwheel Gap area the flood period is difficult of determination, but that area has been assumed to be in flood when the daily run-off exceeds 0.05 in. over the drainage basin, or 1.35 sec-ft. per sq. mile, a rate a little less than one-half the average maximum daily run-off. On the average, the period of flood run-off thus determined embraces about 25 days, generally from May 10 to June 5, or somewhat less than 10% of the time.

Table 5 shows, for both areas, the distribution of the difference between the run-off in the flood periods as defined and that for the remainder of the year. In the Wagonwheel Gap area the maximum increase occurred during the third year after deforestation. There was a decrease during the flood period in the first and last years, and the principal increases occurred during the second, third, fourth, and fifth years. The increase during the non-flood period lessened annually from the third year to the last, as would be expected.

In the Southern California area the maximum increase occurred during the second year after the fire. The increase during the flood period occurred mainly in the first three years and was practically negligible in the last three years. The increase during the non-flood period was annually less from the second year to the last.

TABLE 5.—DISTRIBUTION OF INCREASE OR DECREASE, IN INCHES, IN RUN-OFF DURING THE SECOND PERIOD

							Mar. 15	2.38	Mar. 15	6.00	2.52

conditions from the Southern California area is more than five times greater than the maximum daily discharge from the Wagonwheel Gap area. The average ratio of the discharge of Area *B* to that of Area *A* under natural conditions was 1.19, and under deforested conditions, 1.65, an increase of 39 per cent. The average ratio of the discharge of Fish Creek to that of Santa Anita Creek under natural conditions was 1.55. During the first two years after the fire the maximum ratio was as high as 47.7. For the first four storms occurring in the first year after the fire the average increase was about 1 700%, based on a comparison of ratios. By the second year after the fire the ratios had dropped to practically normal.

In the Wagonwheel Gap area the effect of the removal of the trees was to advance the date of the maximum daily run-off of Area *B* about three days. In the Southern California area, the fire caused no appreciable change in the occurrence of maximum daily discharge.

Fig. 7 shows the actual and computed normal run-off, in second-feet per square mile, of Area *B* and Fish Creek during the typical high-water period occurring three years after deforestation and denudation (April, May, and June, 1922, on Area *B*, and February, March, and April, 1927, on Fish Creek). The shaded area represents the increase or decrease of surface run-off. For clearness an insert is shown with an exaggerated time scale for a few days during the flood peak in the Fish Creek area (Fig. 7(*c*)). It will be observed that practically all the increase on both areas occurred on the rising stage. During the falling stages decreases were common.

Maximum Peak Run-Off.—In the foregoing remarks no reference has been made to peak discharges. In the Wagonwheel Gap area maximum peak discharge results from melting snow, and the ratio between maximum peak and maximum daily discharge is slightly more than 1 : 1. In a semi-arid country, such as the Fish Creek Basin, the maximum discharge depends almost entirely on the rainfall. Immediately after the fire the bare canyon walls were much more conducive to run-off than the plant-covered surface that

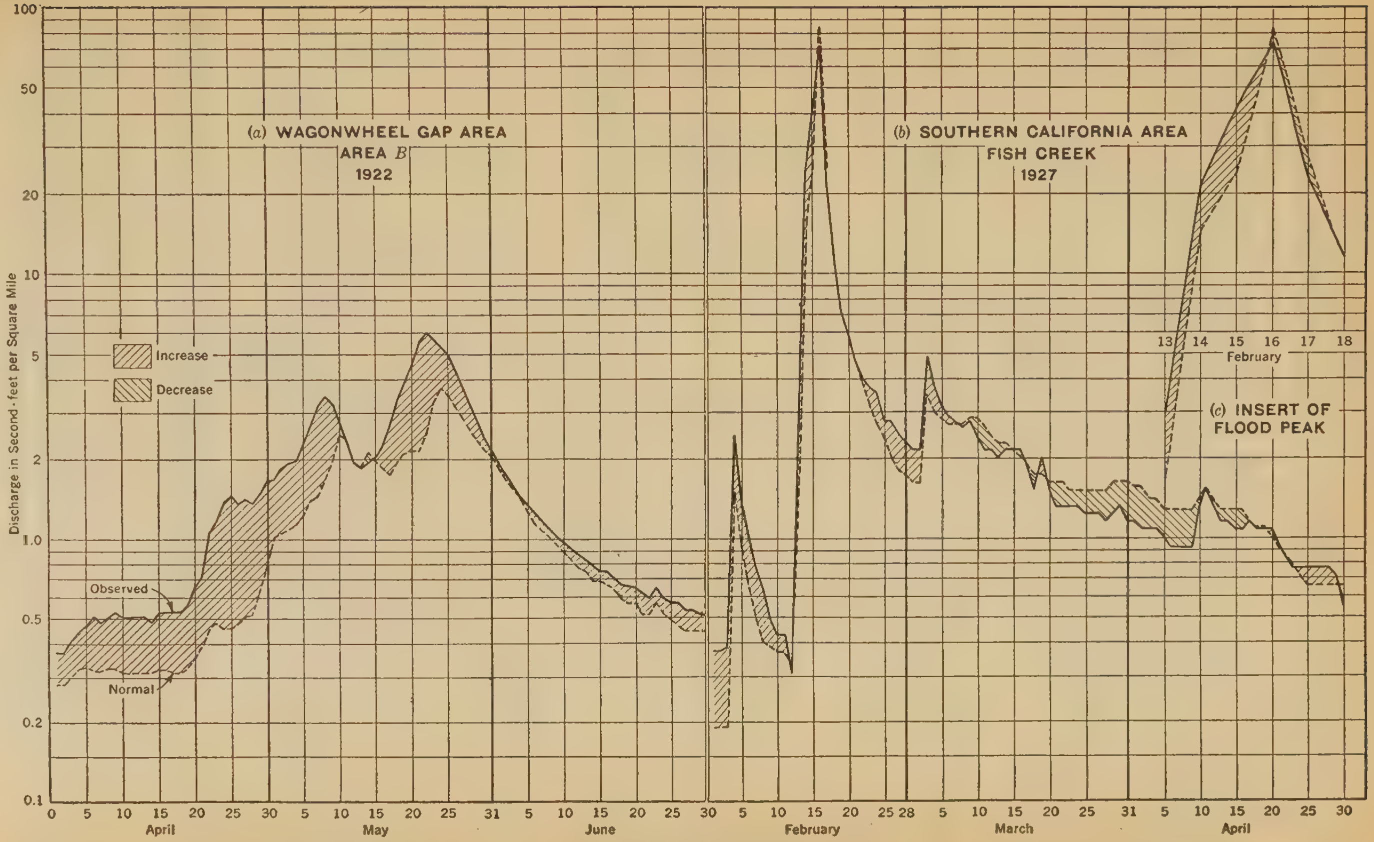

FIG. 7.—OBSERVED AND NORMAL RUN-OFF OF AREA *B* AND FISH CREEK DURING THE STORM PERIOD FOR THE THIRD YEAR AFTER CHANGE

existed prior to the fire. The greatest effect was felt during the first year after denudation. This is well expressed in Table 7, which shows the maximum peak discharges for each year, together with the mean daily discharge for the same day.

During the first period the average peak discharge was 2.5 times the mean daily discharge. In the second period, the first year (1924-25) showed a ratio considerably greater than would have been expected under normal conditions. In the second year, the ratio of the peak to the daily discharge was greatly reduced, but still was larger than any of the ratios of the first period.

Summer Run-Off.—Table 8 shows the run-off for July to October for both areas for both periods. In the Wagonwheel Gap area the ratio of the run-off of Area *B* to that of Area *A* for the first period was 0.93 and for the second period, 1.03. In the Southern California area the ratio of the run-off of Fish Creek to that of Santa Anita Creek for the first period was 0.45 and for the second period, 1.69.

Fig. 8 shows the actual and the computed normal run-off during August and September, the period of low summer run-off, for the third year after the change (1922 for Area *B* and 1927 on Fish Creek). The cross-hatched area represents the typical increase in run-off during the summer.

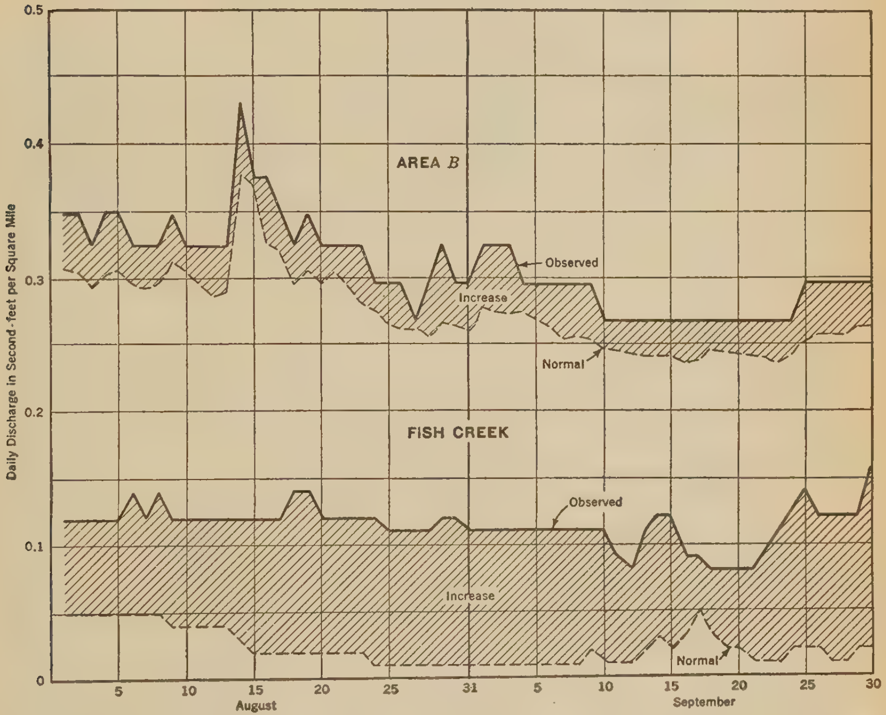

FIG. 8.—OBSERVED AND NORMAL SUMMER RUN-OFF OF AREA *B* AND FISH CREEK FOR THE THIRD YEAR AFTER THE CHANGE

Fig. 9 shows graphically the increase in summer for both areas for the entire period. This diagram shows the accumulated differences in run-off for the two areas for the first period and the accumulated differences between the observed run-off and the normal run-off of both areas for the second period.

Minimum Daily Discharge and Date of Occurrence.—Table 10 shows the minimum daily discharge during the summer for both areas for both periods. Under normal conditions, the minimum rate of discharge in the Wagonwheel Gap area is between seven and eight times greater than that in the Southern California area. The ratio between the minima in Area *B* and Area *A* under natural conditions was 0.98 during the first period; after deforestation, the ratio was 1.10, indicating an increase in run-off of about 12 per cent. Fish Creek was dry at times in four out of the seven years preceding the fire. The ratio between the minima on Fish Creek and Santa Anita Creek based on the seven years was 0.32.

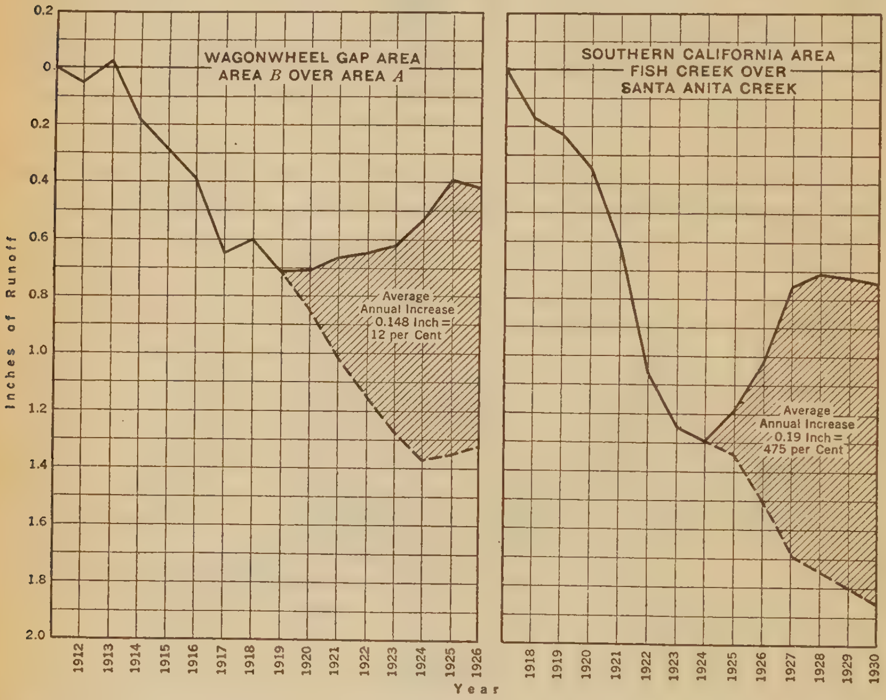

FIG. 9.—ACCUMULATED EXCESS OF RUN-OFF OF AREA *B* OVER AREA *A* AND OF FISH CREEK OVER SANTA ANITA CREEK DURING THE SUMMER PERIOD

After the removal of the forest cover in Area *B*, the date of occurrence of the summer minimum was delayed about five days. After the fire in the Fish Creek area the date of occurrence of the summer minimum was delayed more than a month.

Table 11 shows the minimum daily discharge during the winter for the Wagonwheel Gap area. The average ratio of the minimum in Area *B* to that in Area *A* during the first period was 1.30, or 1.24 if 1915, when the winter minimum for Area *A* was abnormal, is excluded. The ratio during the second period was 1.27 indicating little if any change in winter minima. Inasmuch as the date of occurrence and to a large extent the magnitude of winter minima are a direct result of low temperatures no material change was to be expected. In the Southern California area winter temperatures are not sufficiently low to cause a period of corresponding low run-off.

Erosion: Wagonwheel Gap Area.—In connection with the studies of run-off, quantitative measurements were made, by means of settling basins, of the silt carried by the streams of the two areas near Wagonwheel Gap. During the first eight years the average annual quantity of silt deposited in the collection basin was 691.5 lb. for Area *A* and 568.5 lb. for Area *B*, or 3.15 and 2.85 lb., respectively, per acre. During the seven years after deforestation the average quantities collected were 477 lb. from Area *A* and 3 340 lb. from Area *B*, or 2.15 and 16.7 lb., respectively, per acre, showing about an eightfold increase in the ratio of Area *B*. The higher value represents only a few shovelfuls per acre per year, and, as Messrs. Bates and Henry state,[9]

> "It is only fair to the present discussion to point out that even this large quantity does not represent erosion in the commonly accepted sense of a destructive process."

As to the visible effect, they say:

> "The erosion from the slopes was practically invisible except for one small gully formed from a skid trail, and even the erosion from this appeared to be largely deposited upon a leveled road, without reaching the stream channel."

Erosion: Southern California Area.—On Fish Creek the rapid run-off during the first year after the fire (1924-25) caused considerable erosion to the side walls of the canyon. Beginning December 16, 1924, a series of silt samples were taken in connection with the current meter measurements made at irregular intervals by the U. S. Geological Survey at each of the gauging stations in the burned area. Most of these samples were collected at times when the discharge in the streams was at storm stage. For this reason the figures obtained are considerably above the average for the entire year.

The first rains after the fire washed the ash and loose material from the side walls of the canyon into the stream, to such an extent that by December 16, 1924 (three months after the fire), the entire stream bed had been buried. From a series of pools and rocky rapids, it had become a channel of more or less uniform cross-section with a fairly uniform gradient, sufficient to cause a considerable increase in the velocity. Three current meter measurements made on April 4, 1925, at discharges of 105 to 74 sec-ft., showed mean velocities of 10.5 to 9 ft. per sec. Under normal conditions this discharge would not have had a velocity of more than 2 ft. per sec. As late as June 4, 1925, when the discharge was 3.1 sec-ft., the mean velocity was 4.8 ft. per sec. To this uniform gradient of the stream bed with the increased velocity is partly due the rapid run-off and the unusually large peak storm discharge.

---

[9] *Monthly Weather Review, Supplement 30.*

The silt samples were collected in quart jars. As a rule the mouth of the jar was held half way between the bottom and the surface of the stream. Owing to the shallowness of the stream and the greatly increased velocity, part of the material collected in the samples consisted of the heavier particles which, ordinarily, would form the rolling load, but were then temporarily in suspension.

After the samples had been allowed to settle for three years the results shown in Table 12 were obtained. As a rule, it was possible to separate the ash from the sand, because the sand settled first with the ash on top of it. In most of the samples the division between the sand and ash was well marked. The material called sand in Table 12 consisted mainly of small irregular particles washed off the canyon walls. Included with the ash was some unburned organic matter which usually floated on the surface.

Under normal conditions the erosion in each of the three areas represented in Table 12 is negligible. Prior to the fire there was practically no movement of silt on Fish Creek except during the storm run-off, and by the third or fourth day after a storm the water was practically clear. In the first year after the fire the large deposit of silt from the burned-over area caused considerable damage to orchards, railroads, and highways adjacent to the mountains. In the second year the quantity of silt moved was much smaller and caused little if any damage. By 1930, the silt had been reduced to almost normal, and the appearance of the stream bed was much the same as before the fire.

CONCLUSIONS

The conclusions to be drawn from this paper may be discussed under seven heads, as follows:

1.—Total Run-Off.—Forests did not "conserve the water supply," because after their removal there was an increase in average annual yield amounting to 15% in a mountain area in Colorado and 29% in a Southern California coastal mountain area.

2.—Distribution of Increase in Run-Off.—Contrary to the widely quoted opinion the increase in run-off is not confined wholly to flood periods. In both the Wagonwheel Gap area and in the Southern California area, 52% of the increase occurred during the non-flood period. The flow during the non-flood period is derived from sub-surface storage. The increase during non-flood periods results from either (*a*) increased sub-surface flow and storage; or (*b*) decreased transpiration; or (*c*) a combination of both. More of the precipitation may enter storage after removal of vegetative covering for the following reasons: (1) Less interception by trees, undergrowth, tree litter, and humus; and (2) faster melting of snow with corresponding decrease in evaporation. The gradual lessening of the increase during the non-flood period in both areas after the second or third year may be a reflection of gradual increase in plant growth and corresponding increase in transpiration.

3.—Maximum Daily Discharge.—In the Wagonwheel Gap area there was an average increase of 46% in maximum daily discharge after deforestation. This gain is due to increased sub-surface flow, as practically all the snow had melted several days prior to the date of maximum peak. During flood periods following the snow-melting the discharge in Area *B* uniformly reached a peak three days or more after that in Area *A*, but after the storm of October 5, 1911, the peak in both areas occurred at the same time. This was the only so-called flood that resulted from rainfall and indicates that surface run-off from both areas reached the gauging station at practically the same time. In the Southern California area the four storms occurring during the first year after the fire resulted in an increase of 1 700% in the maximum daily discharge. The peak discharge, which was ordinarily 2.5 times the maximum daily discharge prior to the fire, increased to 16.2 times on April 4, 1925, the maximum peak for the period of record. The floods in the Southern California area usually result from rainfall and represent direct surface run-off.

The removal of vegetative covering clearly increases normal flood heights. Beginning in the second year after the fire on Fish Creek, the flood peak discharges were practically the same as those which occurred before the fire (see Table 7), indicating that the new growth, small as it was, exercised practically the same effect as the original cover in reducing flood crests.

The gradual increase in vegetative covering on the Wagonwheel Gap Area *B* after deforestation had little effect on the increase in flood run-off. (See Table 6.) This was to be expected in that most of the flood run-off in this area reaches the stream through underground channels.

The earlier melting of the snow in the Wagonwheel Gap area resulted in an advance of three days in the flood peak. Where rain passes directly into streams without entering the ground the flood peak for any small element of drainage area occurs so soon after the storm that removal of vegetative cover has little effect on the time element. In the Southern California area the peak was advanced only a few hours.

4.—Summer Run-Off.—It is almost universally believed that forests or vegetative covering will increase summer run-off and shorten the low-water period through the exercise of storage functions. This belief is an outstanding fallacy in so far as these two widely different areas are concerned.

The summer flow (July to October) in the Wagonwheel Gap area showed an average annual increase of 12% during the seven years after deforestation, and the Southern California area, an average annual increase of 475% during the six years after the fire. The absolute average increase of run-off, in inches, for both areas was practically the same. (See Table 7.) The high percentage of increase shown for Fish Creek results from the extremely small summer run-off of that stream under normal conditions. This increase is probably a result of increase in sub-surface storage and decrease in transpiration.

5.—*Minimum Daily Discharge and Date of Occurrence.*—Coincident with the increase in summer run-off there was an increase in the average summer minimum and the period of low-water run-off was considerably shortened. In the Wagonwheel Gap area the average minimum was increased about 12% and the time of occurrence delayed about 5 days. (See Table 10.) In the Southern California area the average minimum was increased more than 400% and the time of occurrence was delayed about 30 days.

6.—*Winter Minimum.*—Deforestation made no appreciable change in the low flows which occurred during the winter in the Wagonwheel Gap area.

7.—*Erosion.*—Erosion results from surface flow. In the Wagonwheel Gap area there was practically no evidence of erosion after deforestation, and this was to be expected because there was little direct surface run-off either before or after deforestation. In the Southern California area complete denudation increased erosion as a direct result of the increased surface run-off. So far as the surface features of the Fish Creek Basin were concerned the erosion did not destroy any present use. However, deposition of eroded material and ash carried by the streams the first year after the fire was materially injurious to agricultural lands and transportation rights of way below the canyon. As it is clearly shown in Tables 6 and 7 that the growth of new vegetative covering by the second year after the fire was nearly as effective in reducing normal flood run-off as the original cover, it may well be argued that if the Fish Creek area had been deforested by cutting of the vegetative cover, as in the Wagonwheel Gap area, without the destruction of the roots and tree litter, the erosion would have been practically the same as with the original vegetative covering.

DEDUCTIONS

If the facts as found are generally applicable to other similar areas which in their natural state support forest growth, then the hydraulic engineer and the water user must weigh such protective influence as forest cover may have in lowering normal flood crests and in preventing or retarding erosion against the detriment resulting from deceased yield and reduced low-water flow during the critical growing period. If the small growth that springs up immediately after deforestation or denudation exercises practically the same effect as forests in reducing normal flood crests and in preventing erosion—without the detrimental effect which forest cover is shown to have on annual flow and flow during the summer low-water periods—then in basins where shortages in water supply are becoming critical or where abnormal expenditures have been made to augment water supplies, the maintenance of forests or reforestation for the "conservation of water supply" may have an effect exactly opposite to that desired.

The writers are lovers of forests and have a keen appreciation of the value of water in the economic development of the United States. The value of the forests as a source of wood for building material and other industrial purposes and as playgrounds is alone sufficient to warrant their preservation and maintenance. Scientifically determined facts apparently do not warrant their development solely for the conservation of water supply. In regions where such supply is a controlling economic factor, careful study is needed to determine whether the value of increased water supply and better-sustained minimum flow which are shown to obtain without forests, does not outweigh the benefits of lowered normal flood flows and decreased erosion produced by forests, especially if these benefits can be obtained by shrubs or other small growth without the loss of water occasioned by forest growth.

DISCUSSION

C. G. Bates,[10] Esq. (by letter).—Since the publication in 1928 of the report[11] of the Wagonwheel Gap stream-flow experiment, the writer has lived in momentary expectation of just such inferences as Messrs. Hoyt and Troxell have made from it. Boldly stated, the authors' conclusion, based on records from two pairs of Western water-sheds, is that vegetation on a water-shed is a detriment to the yield of water. Their revolutionary scheme, brought to its logical conclusion, is to obtain a higher yield of water by means of the simple expedient of removing the vegetation from the water-shed, and with that, eventually, the soil as well. The tone of the paper makes it appear to be directed against foresters who see in the forest cover a beneficial effect.

The writer does not propose to quarrel or quibble over the facts from the water-shed under discussion. By using a different method of analyzing the data obtained from the Wagonwheel Gap experiment, the authors have changed the run-off percentages by a few tenths of 1 per cent. The stream-flow records in Southern California were obtained without adequate precipitation records for the two water-sheds. These are minor points and are immaterial to the main discussion. On the whole, the authors have stated the facts with careful veracity.

However, they did not need to go to all the trouble of trying to prove that forest cover—or for that matter any vegetative cover—is a source of loss of water to the water-shed. Foresters were the first to demonstrate that forests use water in large quantities, possibly in greater quantities than any other form of vegetation, except deep-rooted perennial crops, such as alfalfa. Foresters, again and again, have pointed out the probability that a water-shed, bare of vegetation, is capable of yielding a larger total quantity of water than the same water-shed if covered with a forest, and the denser and more luxuriant the vegetation the greater the loss of water to the water-shed. This is a biological phenomenon no longer in need of proof.

What foresters have claimed and what universal observation since time immemorial has proved is that a forest cover under certain conditions tends to equalize the run-off throughout the year, to increase the storage capacity of the water-shed (especially where the soils are thin or heavy and impervious), and to reduce soil erosion. Foresters have further shown that the beneficial effect of the forest cover varies with the climate, the character of precipitation, and, above all, the character of the soil.

Criticism of this paper is not so much against the authors' conclusions, as they relate to the specific Western water-sheds, but against their attempt to generalize from these water-sheds—which are extreme in character of soil and climate—as to the protective value of the forest under all conditions.

The authors have omitted many facts that are vital to any logical and sane discussion of the subject of forests and stream flow, of "water-shed protection," and of the general utilitarian value of forested *versus* bare lands. While their proposal is carefully guarded and qualified, it tends to leave the impression that sufficient facts have been established to warrant so radical a departure as the elimination of protective forest cover. It is impossible to answer such a proposal in a few words, or even to enumerate more than the most poignant facts.

---

[10] Senior Silviculturist, U. S. Forest Service, St. Paul, Minn.

[11] *Monthly Weather Review, Supplement 30.*

The paper lacks essential information on the geology and soils of the two areas, which would permit a student of such matters to rate the tendency toward surface run-off and erosion and the capacities of the water-sheds for deep ground storage by means of which the streams might be maintained through dry weather. It is not, for example, clearly stated that, in the case of the Wagonwheel Gap water-sheds, the coarse crystalline character of the rock and the resultant porosity and thinness of the soil layer practically precluded the possibility of any surface run-off, and, at the same time, distinctly limited the capacity of the water-shed as a whole for storage in the ground, this so-called soil layer having an apparent average depth of only about 6 ft. In the case of the 3-in. rainfall of October, 1911, the impression is given that the peak of flow on both water-sheds was reached during, and by reason of, surface run-off, whereas this peak flow (although augmented by water falling in the streams) represented merely a saturated condition of the entire water-sheds and played only a small part in the entire flow which occurred subsequently. In such a case as this, and in fact in all the stream-flow phenomena of these water-sheds, it was clearly demonstrated that the surface conditions as modified by the existing forest could play but a very small part. This is far from being the case with mountain water-sheds in general.

It is obvious, of course, that the water-sheds at Wagonwheel Gap do not represent quite the extreme of the porous, completely absorbing type of water-shed. The writer happens to be familiar with various sand-hill regions. In Central Nebraska, for example—what with the porous sand as an absorbing mantle, the lack of dissection, the "pocket" conformation (which is characteristic of all sand dunes), and the great depth and storage capacity of the sand reservoir—the streams that drain the region are extremely steady in their flow, and their annual "floods" probably do not exceed the annual low-water discharges by a ratio of more than about 3 to 1. The water-sheds at Wagonwheel Gap had a high-low discharge ratio (daily, not peak discharges) of 12 to 1, and after deforestation Water-Shed *B* showed a ratio of 17 to 1. It is apparent, therefore, that the porous type of water-shed is not likely to show a ratio of more than 25 to 1, over a long period of years.

The omission by the authors of many pertinent facts with regard to the California areas discussed is decidedly confusing. Nothing is said as to the geology and soils of the two water-sheds. From a slight knowledge of Southern California foothill conditions and from the map presented (Fig. 2), the writer assumes that the lower portions of the two water-sheds have relatively deep but impermeable soils, the surface run-off of which contributes largely to the quick discharges after storms, while the upper portions are relatively rocky and barren. It is probably in the latter portion that most of the absorption of the voluminous winter rains occurs, by reason of which the streams (especially the Santa Anita with its second high area on Mt. Wilson) are maintained throughout most, but not all, of the summer months when no rain is recorded. Because of the fact that many of the winter rains in California are gentle and prolonged, there is, however, for the entire water-shed areas greater opportunity for absorption and storage than occurs with quick summer rains or, in many cases, with the melting of accumulated snow. Probably only in their lower reaches, therefore, do these water-sheds represent that completeness of surface run-off which is associated with arid climatic conditions and which is characteristic of the entire foothill fringe of the Western mountainous area and the adjacent plains and deserts.

There are much more extreme conditions than those cited, as in the case of the extremely impervious shaly or clay soils of the Bad Lands of Dakota and Montana. However, even without this extremely impervious type of soil, essentially all stream flow tends to be in the form of surface run-off and the streams "go dry" completely almost every summer and often throughout the greater part of each year. This is quite largely the result of incapacity to form humus and to enrich the surface soil therewith, which, in turn, can probably be ascribed to dry atmospheric conditions more than any other one factor. In short, all organic litter is oxidized so rapidly that there can be no accumulation, except possibly on a fraction of the area on which brush clumps mechanically hold litter and protect it from the sun. There is no chance of developing on such sites a forest canopy in the true sense, although scattered trees generally establish themselves in the less extreme conditions. In the intervening spaces between clumps of brush or trees, the bare mineral soil is generally exposed, these spaces comprising from 30 to 90% of the entire surface. Inevitably, the result is that surface run-off is never entirely precluded and that any effect from the destruction of the vegetation and existing partial humus mantle changes run-off conditions only in degree and not in kind.

The two types of water-shed drawn upon by the authors, therefore, represent almost complete antitheses, the one showing a high absorbing capacity and a relatively steady flow, and low ratio between flood discharge and summer minima, the other being in the "surface run-off" class, exhibiting little ability to utilize whatever deep storage the soil and geology of the areas provide, and frequently "going dry" in the summer, so that its high-low discharge ratio is in many years infinity, and on the average very high.

Between these two classes of water-sheds lies the greater proportion of the forested areas of the United States both in the Western mountains and in the more humid East. Although, of course, depending on the manner in which the surface cover has been treated, the high-low ratios for a large proportion of the water-sheds in the country run from 50:1 to 150:1. Under the more humid conditions which permit the actual development of a normal forest, and which, at the same time (by the more rapid processes of weathering), rarely permit extremely porous soils to exist, an entirely different situation exists. It seems undeniable, if one accepts human experience and observation as worth anything at all, that in one important particular the stream-flow situation is different from that in the two cases cited. This is in the matter of increased, rather than decreased, summer flow as a result of the long-time effects of forest cover and of humus upon the absorptive capacity of the soil.

If, for example, one can picture the difference between 3% run-off from a well-forested area, and 50 to 80% run-off from burned, pastured, and cultivated areas, during rains which pour from 1 in. to 3 in. of water upon the soil in as many hours, one obtains the basis for an entirely different conception of the value of forest cover. This value is obtained, necessarily, by deep storage of the additional water which gets into the ground through a good layer of humus. Much of this storage is undoubtedly beyond the reach of tree roots, so that the surface layer may become completely dried through root absorption, and still the deeper reservoir remains filled and supplies springs throughout long periods of dry weather. It is obvious that this effect on the low-water flow (even admitting a decrease in total annual run-off) arises solely through increased surface absorption and the existence of a potential large reservoir in the deep soil and rock layers. In recent years, and from a multiplicity of sources, the facts regarding the increased absorption due to forest humus have been established beyond a shadow of doubt. The work[12] of Dr. W. C. Lowdermilk, too, has presented an entirely new and much more sane conception of the function of humus in water absorption by soils, so that one no longer thinks of the humus layer as a reservoir in itself, but as supplying the channels through which water may penetrate an otherwise largely impermeable soil.

That all these facts have not been brought together under one comprehensive water-shed experiment, in which the year-long regimen of streams was studied, is unfortunate, but it should scarcely destroy sanity. In fact, the weight of observation on this point is so great that it certainly cannot be set aside because of conflicting observations under conditions of arid climates and limited storage possibilities. The conditions cited by the authors are in no sense "normal," although they may possibly be representative of considerable areas in the West.

The authors, while admitting the occurrence of severe erosion within a few months after the Fish Creek fire (which erosion filled the stream channel with débris and did "considerable damage to orchards, railroads, and highways" below the water-shed), tend to minimize its importance and state in their "Conclusions" that "so far as the surface features of the Fish Creek Basin were concerned the erosion did not destroy any present use." This bland statement of the harmless effect of one fire begs the question and is misleading. Erosion is a time-consuming process—it normally proceeds almost imperceptibly so far as "surface features" are concerned, and destructive erosion gains headway only after the "harmless" type of erosion has proceeded for a considerable time. Messrs. Hoyt and Troxell have shown that the beneficial effects of the fire denudation began to decrease after a couple of years. It would require repeated fires and almost complete elimination of all vegetative cover to maintain such benefits to stream flow. That destructive erosion would soon follow such treatment is a foregone conclusion, and there is only one logical outcome to the use of the methods proposed by the authors for obtaining greater stream flow—to remove the entire soil mantle of the water-sheds and with it every obstacle to quick surface run-off.

---

[12] "Influence of Forest Litter on Run-Off, Percolation, and Erosion, *Journal of Forestry*, Vol. XXVIII, No. 4, April, 1930.

It seems scarcely probable that even the people of Southern California would place such stress on increased population and increased water supplies that they would choose to have their entire foothills region assume the barrenness of the upper slopes of Mt. Wilson. Nor is it conceivable that any engineer will argue, in view of the reservoir difficulties which are daily being brought to his attention, that surface run-off carrying a heavy burden of silt is equivalent in practical usefulness to a corresponding volume of clear, subsurface flow. There may be communities in dire need of additional water, but it is not believed there are any that can afford to obtain it by a method so wholly destructive in its design.

As far as the general proposition of "protection forests" on mountainous water-sheds is concerned, progressive erosion as the result of deforestation or complete denudation is the crux of the situation. It is rarely that areas will be found as immune to surface run-off and erosion as those at Wagonwheel Gap, and it may be seriously questioned whether these areas would stand repeated burnings, and (as a logical sequence) grazing of the herbaceous vegetation which sprang up, without showing a great change in respect to these soil-destroying processes. At the other extreme, there is, chronically, some erosion despite the efforts of a feeble vegetative cover to maintain itself, and with the kinds of soils which usually prevail in the foothills areas, unimportant erosion may quickly develop into deep gullying. In areas of the intermediate class, there will be no less a tendency toward soil loss once the forest is removed, except as delayed by the greater depth of humidified soil and the richer vegetation which that soil and the more humid conditions will support. Once this "reserve" has been lost through a conscious effort to keep down the forest, the unprotected soil will give way in much the same manner.

It is for the conservation of the soil resource quite as much as the water resource or timber resource that the forester argues the need of "protection forests." In young mountainous regions, Nature has decreed that the one is indispensable to the other and that the building of soil in the first instance is dependent on the roots of trees and on lower forms of vegetation which grow on rock surfaces; then, on the chemical action of the organic matter which they deposit; and, finally, upon the protection from erosion which is furnished by the complete humus mantle. The forest, in turn, can develop as individual units and, finally, as a solid "stand" only as these soil-forming steps progress and as the storage capacity of the soil increases. Eventually, deep soil deposits are obtained which far surpass in storage capacity the requirements of the protecting forest.

Has the time arrived when Man may assume the audacity to start reversing these great constructive processes of Nature, for the sake of a temporary benefit, to water a few paltry additional acres of crops or to permit a few more people to congregate in the cities? The Engineering Profession is not lacking in audacity, and it frequently defaces and defies Nature for the sake of a temporary gain. When such a proposal as that of Messrs. Hoyt and Troxell is being seriously put forward, it is time for the profession to ask itself whether or not it is truly giving heed to the interests of humanity.

J. E. WILLOUGHBY[13] M. Am. Soc. C. E. (by letter).—This paper is conclusive as evidence that forests do not conserve the water supply and that when the forest cover is replaced by small growth, the effect on flood crests is negligible. The investigations were made on small areas; nevertheless, the conclusions can be applied to larger streams and for areas differing widely in physical characteristics.

Extreme flood conditions in the streams flowing across the South Atlantic Coastal Plain are caused by tropical storms, and these storms are variable in route traversed, rapidity of movement, and quantity of rainfall. The forests, or lack of forests, are not factors of importance in the flood discharge. It is of interest to record the maximum discharge of the Savannah River at Augusta, Ga. This city is at the Falls of the Savannah and is on the western edge of the Coastal Plain. The water-shed up stream is a rolling plateau in which the streams occupy deep ravines. The plateau about the head-waters of the Savannah is broken by hills and low mountains. The virgin forests were cut long ago for lumber and the area is extensively farmed. There has been an approximately uniform increase in the area under cultivation, modified to some extent by the changed economic conditions following the Civil War between the States. The record for the Savannah River at Augusta, in extreme floods, is as follows:

Year	Maximum discharge, in cubic feet per second.	Year.	Maximum discharge, in cubic feet per second.
1796	360 000	1928	226 000
1852	255 000	Sept., 1929	374 000
1888	300 000	Oct., 1929	383 000
1908	307 000		

The record of this great river sustains the conclusion that the cutting away of the forests does not cause an increase in the flood discharge. In this connection, it is worth while to remember that a principal factor in the destruction of the small growth cover that follows the cutting of the virgin forests, is the policy of the forest conservationists of keeping annual fires from the cut-over forest. That policy permits the accumulation of débris on the forest floor from year to year. The accumulation soon provides fuel sufficient to produce a fire intense enough to destroy the smaller growth, and thus prevents the quick reforestation of lands unsuitable for cultivation. In the dry year, 1931, much of the young forest growth was destroyed in North Carolina, South Carolina, and Georgia, as a result of the application of the prevailing forest-conservation theories.

[13] Chf. Engr., A. C. L. R. R., Wilmington, N. C.

A. L. SONDEREGGER,[14] M. AM. SOC. C. E. (by letter).—This paper forms a timely and valuable contribution to the knowledge of the function of the forest relative to stream flow. The writer agrees with the authors in their deductions, however, having clearly in mind that these deductions apply to water-sheds with residual, and, hence, with relatively shallow earth cover, where deep penetration of rainfall cannot take place. Possibly special stress should have been laid upon this feature, because water-sheds and forest growth on formations that originate in glacial moraine, or that consist of alluvial fills, may perform a function distinctly different from that described in the paper.

The writer is familiar with Fish Canyon water-shed and its steep slopes covered with residual soils, which probably average less than 8 ft. in thickness. It is also inferred from the description of Water-Sheds *A* and *B*, at Wagonwheel Gap, Colo., that the soil is not of sufficient depth to permit of deep penetration beyond the reach of roots. The statement[15] has been made that the augite-quartz-latite that comprises the entire foundation of the two watersheds breaks down, by reason of its fine, crystalline structure, into a rather fine and compact clayey loam. The report states, however, that because of the steepness of most of the water-shed slopes, this quality is only partly developed; that is, steady sheet erosion prevents the accumulation of deep masses of soil and causes rock fragments to comprise a considerable proportion of the mass, sometimes as much as 50% of the first 4 ft. of soil. Furthermore, erosion and leaching tend always to rid the soil of clay and silt, leaving the coarse sand. The result on all the steeper slopes is a quite permeable and well-drained soil layer, the depth of which has never been directly investigated on the main slopes. This description, the steep slopes, and the relatively young and slender tree growth, indicate a shallow earth cover.

The intensive development that has taken place in the semi-arid West during the 20 or more years since about 1910 has brought about, in many regions, a demand for water supplies in excess of those naturally available. It is realized that the evapo-transpiration requirements of the water-shed cover may consume from 40% to 100% of the seasonal precipitation, so that the run-off available at the foot of the range may be only a fraction of the meteoric supply. It has also become apparent that flood waste is, in many cases, only a relatively small portion of the total run-off, that the cost of its conservation is economically prohibitive, and, from the standpoint of water supply, that it is of minor importance.

---

[14] Cons. Engr., Los Angeles, Calif.

[15] *Monthly Weather Review, Supplement 30*, p. 3.

Salvage of even a portion of evapo-transpiration losses being more promising, there have been, therefore, many proposals for the improvement of the water-shed with a view of increasing its water yield. Broadly speaking, they may be classed in two groups[16]:

First.—"Super-forestation" to the effect of producing a denser growth of native or other vegetation on the water-shed, in order (*a*) to "keep the water in the water-shed," as the saying goes; and (*b*) to induce more copious precipitation.

Second.—"Light deforestation" to restrict the vegetation to a minimum compatible with effective prevention of erosion, the intention being to diminish the evapo-transpiration requirements of the cover.

"Super-forestation" may be described as an effort to utilize the storage capacity of the water-shed to its maximum by increasing the absorption of precipitation and preventing flood waste by means of profuse vegetation. It presents, therefore, the logical solution for water-sheds overlying deep alluvial fills or glacial moraine, in regions enjoying abundant precipitation, where water supplies are required mainly for domestic purposes and depend upon underground supplies, springs, or unregulated stream flow. Forestation of bare water-sheds would have a similar beneficial effect under such conditions.

In the Middle Western and Middle Northern States, climatic conditions and the deep alluvial deposits of the plains or the moraines of one-time glaciated areas generally favor forestation as well as super-forestation. In semi-arid regions, super-forestation may be desirable if surface storage is lacking or flood run-off is abnormal because of a meager plant cover. Under the latter condition, however, the increased consumptive use of a densely grown water-shed cover has a tendency to reduce seepage run-off because, generally, vegetation is exceptionally tolerant. Vegetation is capable of sustaining growth in wet years almost as long as the moisture supply holds out, so that, in some measure, evapo-transpiration requirements may be proportionate to the density of vegetation.

It is quite apparent that super-forestation has its natural limitations because by natural selection the density of the existing vegetation, as a rule, is the one best adapted to the prevailing climatic conditions. Attempts to "make two trees grow where formerly grew one" over large areas, therefore, would have little chance of success. On the other hand, the forestation of bare areas overlying deep earth deposits unquestionably will promote percolation and increase ground-water supplies and normal stream flow at the expense, however, of a lesser total run-off. This result, under certain conditions, may also be desirable in semi-arid regions.

Practical proposals of super-forestation include the planting of trees in cut-over or burnt-over areas and the substitution of chaparral by trees. As a means of retarding surface run-off and inducing seepage, a dense growth of brush is likely to be as effective as a forest. Whether or not trees would grow in the chaparral zone may depend upon local conditions.

---

[16] Unpublished report by the writer to the Water Conservation Committee of the Irrigation Division.

"Light deforestation" has been proposed with a view of reducing evapo-transpiration losses of the water-shed cover, and correspondingly increasing the water crop. It may present a logical solution for water-sheds having a shallow earth cover, in which roots penetrate to underlying bed-rock, and the seeped ground-water remains exposed to abstraction by plant growth until intercepted by surface drainage. Under such conditions, a large percentage, if not all, of the seepage is consumed by plant life, reducing the seepage run-off to only a fraction of the meteoric supply. In a general way, this was the condition prevailing in the water-sheds of Wagonwheel Gap, in Colorado, and of Fish Canyon, in Southern California.

The immediate effect of light deforestation is a greater surface run-off and lesser rainfall penetration, and the subsequent effect, a lesser evapo-transpiration loss. This result may be desirable in cases where the water demand exceeds the natural run-off and where storage of flood waste is practicable either in surface reservoirs or underground in the flood-plain. It applies to a large portion of the water-sheds of the semi-arid West.

Of the many proposals to effect light deforestation, the following deserve to be mentioned: The systematic burning of the underbrush of forested areas and of the chaparral of brush-covered water-sheds; the substitution of heavy water-using species of brush or trees by others of lesser consumptive use and the cutting of trees growing along watercourses, such as willows, alders, and sycamores. It is believed that measures of this kind would contribute to a conservation of water supplies. Whether the gain would justify the risk involved, or the destruction of the charm of the shaded brook, is quite another question.

Considering the matter strictly from the standpoint of conservation of water supply, both groups—super-forestation and light deforestation—have their merits, depending upon climatic conditions and the formation and depth of subsoils.

It may be of interest to note that super-forestation (also forestation) is constantly urged and promoted in the semi-arid Western regions with a view of increasing water supplies under conditions that are inimical to the success of the plan; that is, for steep mountain water-sheds with a shallow cover of residual soils and a mean rainfall less than the optimum use of the native vegetation.

Upon closer analysis it is found that the idea of super-forestation has been brought West, as an adjunct to the great process of interstate migration which has been so active during the twenty years (1912-1932), particularly from the prairie States. Most of the population of California, for example, settled in that State within the last generation, and having firmly in mind the benefits derived from forestation and super-forestation in their native Middle Western States, are now promoting the plan with remarkable tenacity, for conditions quite different. It is probable, for example, that the suggestion of replacing chaparral by forest originated with these people, under the claim that trees are better suited to keep the water in the water-shed and are inducive of more copious precipitation. The plan has been tried in Southern California, but failed because the trees would not grow without irrigation (except in a few favored spots).

From the water-supply standpoint, the plan has no merit: First, because the trees, like the brush, season after season, would consume the field capacity of the soil within the reach of their roots, with no chance of salvaging seepage water; and, second, because a fire (and fires do occur) would destroy the tree growth. Then, unless new trees were planted, the water-shed would remain bare until, in the course of years, a new growth of chaparral had returned it to its original condition. On the other hand, burned-over brush areas naturally recuperate within two or three years to the point at which the new growth, together with grasses and herbs, protects the soil from erosion. It is a fact that the ordinary brush fire neither destroys the roots nor burns up the seeds of herbs and grasses that seem to be buried in the soil, so that with the first rains an effective start is made toward the creation of a protective cover.

J. C. STEVENS,[17] M. AM. SOC. C. E. (by letter).—After many years of guessing and useless argument some authentic information has been produced at last as to the effect of forests on stream flow. The final conclusions are exceedingly simple. They might have been—in fact, actually were—anticipated many years ago. The forest, like every other vegetable crop, consumes large quantities of water for its growth. Unlike small plants, however, it also dissipates large quantities of water by mechanical means. It prevents a substantial portion of rain and snow from reaching the soil, permitting rapid evaporation from branches and leaves. When the forest is removed, the water thus consumed by it appears as run-off. As new growths appear the run-off gradually diminishes again in proportion to this crop and mechanical consumption. Two widely separate tracts cited by the authors under diverse climatic conditions attest emphatically to this fact. All other effects, such as advance or delay of maximums and minimums, are quite trivial, uncertain, and inconsequential.

Writers on this subject have been to exquisite pains to avoid the acknowledgment of the foregoing simple conclusion. Why all the feverish urge to prove that forests are intimately connected with an improvement of the regimen of streams? Why must simple facts be submerged under an avalanche of conjecture when they fail to meet preconceived specifications?

The answers are perhaps best stated by Dr. John Ise[18] in recounting the history of the Weeks Bill which was introduced in Congress in July, 1909, and passed in February, 1911. About $9 000 000 was appropriated for the purchase of forest lands in the Appalachian and White Mountains "for the protection of the water-sheds of navigable streams."

The debate over the Weeks Bill consumed one and one-half years of Congressional and National attention. It marked an epoch in the history of the forest policy in the United States. Dr. Ise declares that the main purpose of this Act in emphasizing the assumed relation of forest conservation on the navigability of streams, was merely to meet the question of constitutionality. He points out that there is no agreement among authorities as to the effect of forests in equalizing water flow; that the benefits have been greatly exaggerated by many writers; and that such benefits were grossly exaggerated in the debates in Congress.

[17] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

[18] "The United States Forest Policy," by John Ise, Yale Univ. Press.

The following is an example of the gross exaggeration prevalent during the heyday of militant conservation:[19] "The connection between forests and rivers is like that between father and son. No forests, no rivers."

Another calamitous prophecy was to the effect that "when our forests are gone the streams will dry up, the rivers will cease to run, the rain will fall no more, and America will be a desert!"[20]

In 1910, the writer was employed on the famous "Smoke Case" by the Anaconda Copper Mining Company to make a study of the effect of forests on stream flow, climate, and soil, with particular reference to conditions in the Deer Lodge National Forest surrounding the huge Washoe Smelter, at Anaconda, Mont. This study was prompted by a suit instituted by the U. S. Forest Service to enjoin the Company from further operation of the smelter on the grounds that the smoke was destroying the surrounding forest and that the destruction of the forests would result in damages amounting to untold millions to the valley of Clark Fork River in increasing its floods, diminishing its minimums, and filling its valley with the soil from countless acres of denuded forest areas. The picture set up in the complaint was very gloomy.

The writer entered this study with an open mind, if anything, somewhat biased in favor of the forest-water-supply theory by reason of having absorbed most of the propaganda extant at the time. He gathered all the long-time stream-flow records in the world on which decided changes in forest cover have taken place. Among them were the Tennessee, Ohio, Ottawa, Murray (Australia), Merrimac, Sudbury, and Croton Rivers. No changes in regimen that by the greatest stretch of the imagination could be attributed to changes in the forest cover, could be detected. Any cyclic variations disclosed in run-off was accounted for readily and simply by similar variations in climatic factors. The generalized results of this study have been published.[21] After this study the writer felt fully convinced that the forest-water-supply theory belongs in the catalog of political expediencies rather than that of the sciences. Man's efforts to change the regimen of streams are puny and futile. The governing factors belong to forces far beyond his power to control.

Recently, the writer had occasion to go over a part of the lands around the Washoe Smelter, that were the subject of such intense study twenty-two years ago. The smoke has killed practically all the trees leeward of the smelter for many miles. Of course, Government and private owners have been amply compensated for their loss. The streams flowing from this graveyard of trees still run crystal clear and sparkling. There is no diminution in the supply as far as ocular evidence can be trusted. There is no more evidence of soil erosion than existed while the trees were alive and green.

[19] "The Fight for Conservation," by Gifford Pinchot, Doubleday, Page & Co., New York, 1910.

[20] *Scrap Book*, September, 1908.

[21] "Forests and Their Effect on Climate, Water Supply, and Soil," by J. C. Stevens, M. Am. Soc. C. E., *Journal*, Assoc. of Eng. Societies, July, 1913.

Every one loves the forests; every one is glad they are in the hands of the Government and is grateful that they are being conserved for this and future generations. Their value for timber supplies, for recreational playgrounds, and to soothe æsthetic senses are ample and cogent reasons for preserving that control. If it was necessary once to attribute to them properties they do not possess, in order to "kid" the people and Congress into doing the thing that everybody wanted done anyway, that necessity has passed. Forest control is now a blessed fact. Is there any further necessity to keep up the farce?

HARRY F. BLANEY,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Although European and American experimenters have been observing the influence of forests on stream flow for many years, no final conclusions covering the entire subject have been definitely established.

One needs only to review some of the voluminous literature on this subject to be convinced that there is a great difference of opinion among authorities. For instance, some believe that because rainfall is most abundant where forests grow, that they exert an important influence on the amount of precipitation, and that it is a definitely established fact that the destruction of forests is followed by a decrease in rainfall and drying up of streams and springs. Others have reached the conclusion[23] that "precipitation controls forestation but forestation has little or no effect upon precipitation. * * * The run-off of our rivers is not materially affected by any other factor than precipitation."

Thus, any new data that may throw additional light on this perplexing subject, are welcomed by the engineer, forester, and agriculturist. The authors are to be complimented on their excellent paper. The writer will confine his discussion to the part pertaining to Southern California, as most of his experience has been in that section.

Some investigators have been forced to the conclusion that "in respect to run-off, each stream is a law unto itself." This, undoubtedly, is true in many instances. There are so many complex factors influencing stream flow that the problem of determining the effect of forests on run-off by comparison of the discharge of streams of forested and denuded water-sheds is extremely difficult. Run-off is influenced so largely by the character of the precipitation, topography, elevation, geology, vegetation, and artificial control that quantitative measurements of the effect of forests on the flow of streams by comparing forested and deforested areas are usually open to criticism. However, the authors have adopted ingenious methods to overcome most of these objections.

[22] Irrig. Engr., U. S. Dept. of Agriculture, Los Angeles, Calif.

[23] A report on "The Influence of Forests on Climate and on Floods," by Willis L. Moore, H. R., U. S. Committee of Agriculture, 1910, p. 37.

A discussion of "forests and stream flow" would not be complete without including the subject of consumptive use of water by native vegetation. That a gap exists between the quantity of rain falling on a given water-shed and the total run-off is clearly indicated by an analysis of data shown in Tables 2 and 3. For the period under consideration, the minimum annual run-off of the Santa Anita Creek occurred in 1924-25 and was 1.24 in., or about 6% of the total precipitation. In other words, the precipitation unaccounted for in 1924-25 was 20.67 in., or 94%; while in 1921-22, it was 30.62 in., or 51 per cent.

Whether this difference was due entirely to evaporation and transpiration losses is a debatable question. The authors state that it is doubtful whether any under-flow passes either station. Run-off, according to Meyer,[24] constitutes the residual precipitation after evaporation, transpiration, and deep seepage losses have been supplied, and the demands of evaporation and transpiration require from about 15 to 25 in. of precipitation per annum. Zon states[25] that the water consumed by the forest is nearly equal to the total annual precipitation—in cold and humid regions less, and in warm and dry regions somwhat greater.

In evaluating the evapo-transpiration losses of drainage basins, such as Santa Anita Creek and Fish Creek, it is desirable to divide the water-shed into two areas: (1) Drained slopes; and (2) canyon bottom. The "drained slopes" or sides of the canyon usually support chaparral, while in the "canyon bottom" water-loving trees, such as alders, willows, and sycamores, predominate. Evapo-transpiration losses from "drained slopes" start with the first rains in the fall and continue throughout the rainy season into the summer, until all the moisture in the soil, available for plant growth, has been extracted. It is difficult to determine these losses by field measurements. However, the consumptive use of water by brush cover on the valley floors has been successfully measured by soil-sampling methods.[26] Evapo-transpiration losses in the "canyon-bottom" area continue throughout the summer months, or as long as water is supplied from deep springs or is available from storage in alluvial fill. Under favorable conditions these losses can be measured.

The conservation of water by removing brush from the "drained slopes" is remote; the resulting damage by erosion would more than offset the value of the water saved. However, conservation by reducing the evaporation and transpiration losses in "canyon-bottom" areas of a water-shed is more promising. The City of San Bernardino, Calif., is accomplishing this by piping water out of the stream channel. In Southern California this expense is justifiable since title to water diverted by gravity from streams has a market value of from $2 000 to $4 000 per miner's in. (continuous flow), or $100 000 to $200 000 per sec-ft., depending on its use.

[24] "Elements of Hydrology," by Adolph F. Meyer, M. Am. Soc. C. E.

[25] "Forests and Water in the Light of Scientific Investigation," by Raphael Zon, Forest Service, U. S. Dept. of Agriculture, 1927, p. 20.

[26] "Rainfall Penetration and Consumptive Use of Water in the Santa Ana River Valley and Coastal Plain," by Harry F. Blaney, Assoc. M. Soc. C. E., C. A. Taylor, and A. A. Young, Assoc. M. Am. Soc. C. E., *California State Bulletin No. 33.*

Little information is available as to the quantity of water lost in the bottom of canyons through evaporation and by transpiration from vegetation. In the spring of 1929 some experiments were conducted by the U. S. Bureau of Agricultural Engineering on the "consumptive use of water by native vegetation along stream channels"[26] in Temescal Canyon, 4 miles southeast of Corona, Calif. The vegetation consisted of willows, tules, and kindred moist land growths. For a 30-day period, from April 28 to May 27, inclusive, the total evapo-transpiration was 12.9 acre-in. per acre.

In 1931, this investigation was extended to Coldwater Canyon[27] near Arrowhead Springs, Calif., and methods were developed to measure the evaporation and transpiration losses in canyon bottoms.

One of the methods used was to measure losses of stream flow between two bed-rock controls, located about 2 100 ft. apart in the canyon. The approximate elevations of these controls above sea level are 2 300 and 2 500 ft., respectively. The canyon between the controls is narrow and has precipitous sides, with the bottom width ranging from 30 to 50 ft., and the vegetation is mostly alders, with some sycamores, bay, oak, and herbaceous growth. During the period of record, there were no visible indications of water reaching the section under study other than that passing the upper control. At each control a low concrete dam was built across the stream channel on a bed-rock foundation. A 3-in. Parshall measuring flume, equipped with a Stevens type L water-level recorder, was placed at one end of each dam for the purpose of measuring the flow of water passing into and out of the experimental section of the canyon between the controls. At first, values for the gauge height for each hour were used in computing the volume of water passing the two controls. The daily loss between controls was obtained by subtracting the daily volume of water passing the lower control from the daily volume passing the upper control. This proved to be a lengthy and laborious process, and in order to eliminate a large part of this routine work, a flow recorder was attached to the water-stage recorder. This flow-recorder attachment consists essentially of a spiral cam that solves the flow formula mechanically.

The loss of water per day between the upper and lower controls may be obtained directly by superimposing the two flow-recorder charts, one from each control, and measuring the area between the two curves by planimeter. This area represents the daily loss between the controls, and when multiplied by the proper constant can be converted into the hydraulic units desired.

---

[27] An unpublished Progress Report on Evaporation and Transpiration Studies in Coldwater Canyon, by Harry F. Blaney, Assoc. M. Am. Soc. C. E., C. A. Taylor, and H. G. Nickle, Jun. Am. Soc. C. E., Bureau of Agricultural Eng., U. S. Dept. of Agriculture, 1932.

The relative amounts of the indicated losses that are chargeable separately to evaporation and transpiration are difficult to determine. However, Rohwer[28] has indicated that the rate of evaporation is relatively low when the temperature of the water is below that of the overlying air. This condition exists in Coldwater Canyon throughout the growing season as the water comes from cool springs and is shaded as it flows through the stream channel of the canyon. Thus, evaporation is small, and the loss indicated by the daily drop in stream flow is due principally to transpiration.

From the Coldwater Canyon measurements it is estimated[27] that the consumptive use of water by canyon-bottom vegetation during the 6-months summer season, May to October, was 45 acre-in. per acre, 238 acre-in. per mile of canyon, or a depth of 0.10 in. over the water-shed per mile of canyon.

Referring to data given by Messrs. Hoyt and Troxell, the average run-off from Santa Anita Canyon during the six summer months, May to October, inclusive, for seven years ending September, 1924, was 1.19 in. in depth over the entire water-shed. The stream in the Santa Anita Canyon (including the tributaries) is estimated to be 13 miles long. Assuming that the data obtained from the Coldwater Canyon experiment can be applied to Santa Anita Canyon, the use of water by canyon-bottom vegetation would be 1.30 in. in the latter. This amounts to 109% of the average run-off for the same period or, in other words, the run-off for the six summer months would be increased 109% if no water was used by the canyon-bottom vegetation.

In like manner, an estimate can be made of the summer consumptive use of water in Fish Canyon. From the Fish Creek water-shed for the 6-months' period—May to October—for seven years ending September, 1924, the average run-off in depth, in inches, was 0.90. The stream is estimated to be 10 miles in length, and the use of water by canyon-bottom vegetation, 1.0 in., or 111% of the average run-off for the 6-months' summer period for seven years preceding the fire. This result is somewhat surprising since the authors show an annual run-off of only 1.00 in. in Fish Canyon the year before the fire, and an annual normal run-off of 1.07 in. the year following the fire. In other words, for these years the summer use of water by canyon-bottom vegetation was 100% of the total annual run-off. The increased run-off for the six months during the summer following the fire was only 0.40 in. Thus, if all the water used by canyon-bottom vegetation during the summer months could be conserved by piping it out of the stream channel, the increased run-off would be 1.0 in., or 250% of the increased run-off resulting from the burning off of the water-shed. However, it is doubtful whether more than 80% of the water consumed by the canyon-bottom vegetation could be saved.

In closing, the writer would like to call attention to the serious problem of erosion in Southern California. The data given in Table 12 of the paper illustrates clearly the large quantity of silt carried by a stream after the vegetation has been burned off a small water-shed. It should be pointed out that the rainfall that year was about 30% below normal; and, thus, only a minimum of damage was done. However, in a year like 1921-22, with an annual precipitation of 60 in., or twice the normal, the amount of damage due to erosion would have been tremendous if the chaparral cover had not been there to prevent it.

---

[28] "Evaporation from Free Water Surfaces," by Carl Rohwer Assoc. M. Am. Soc. C. E., *Technical Bulletin No. 271,* U. S. Dept. of Agriculture, December, 1931.

DANIEL W. MEAD,[29] HON. M. AM. SOC. C. E. (by letter).—This excellent paper presents the most exact and conclusive measurements that are available of the effect of deforestation and denudation of drainage areas on the flow of streams. The only uncertainties in the conclusions as regards the streams discussed seem to be in the relative quantity and distribution of the rainfall on the areas of the Santa Anita and Fish Creeks in Southern California, and the possible different effects of such variation of rainfall on the comparative flow of these streams before and after the time when deforestation and denudation occurred. It will be noted that the only rainfall stations available for these areas are at Mount Wilson and at the Santa Anita Ranger Station, both of which are west of Fish Creek and cannot represent the rainfall accurately on that drainage area which, in each rainstorm, would probably vary somewhat from the rainfall at these stations just as the rainfalls at the stations vary one from the other. The increase in flow from the drainage area of Fish Creek, however, is so considerable that there can be no question as to the actual increase in flow resulting from the deforestation and denudation of the Fish Creek drainage area, although the actual quantity seems somewhat uncertain.

The rainfall measurements on the Wagonwheel Gap areas are much more complete and represent the actual conditions as well as they could reasonably be determined. In the writer's opinion there can be no doubt as to the essential validity of the general conclusions that will be drawn from these data, that, in general, increased flow will follow deforestation and denudation on small drainage areas where other factors remain the same.

It is obvious that: (1) The relative results of deforestation or reforestation in each case must depend upon the physical and climatic factors that prevail on the areas from which such results obtain; (2) in applying these data to other small areas, the comparative physical and climatic factors of such areas must be considered; and (3) any variation in such factors will necessarily modify the results to be expected.

In extreme and rare cases it is possible that deforestation, and especially denudation, of small drainage areas might even reverse the results obtained under the conditions considered by the authors.

It is particularly worthy of note that the drainage areas considered in the paper are comparatively small (Area *B* of Wagonwheel Gap, 200.4 acres; and area of Fish Creek, 6.50 sq. miles), and that while the results of deforestation and denudation are quite marked on these limited areas, it is obvious that, as affecting the larger drainage areas of which they are a part, the results might be quite insignificant and indistinguishable. Therefore, it is still necessary to utilize inductive reasoning in discussing the application of the data from these small areas to the larger areas of great rivers.

---

[29] Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin; Cons. Engr., Madison, Wis.

As a basis for such reasoning, it is necessary to consider first principles as they are demonstrated by the simplest experiments and examples that are available.

Rainfall.—It is quite obvious that the principal factor that affects stream flow is the quantity and distribution of the rainfall on its drainage area. Evaporation (including plant transpiration), percolation, and run-off are dependent on the physical and climatic conditions on each drainage area. Each increases in general as rainfall increases, although not in direct proportion. The departure from direct proportion; that is, the difference between rainfall and evaporation, percolation, or run-off measures the effect of temperature, humidity, wind velocity, distribution of rainfall, and other minor factors. When the rainfall occurs in light showers, the proportion lost in evaporation and transpiration is greatly increased; and, in most places in the United States, if the annual rainfall were distributed equally over each day of the year, it is doubtful whether any of it would flow away in streams unless it accumulated as snow or ice during the winter and melted suddenly on the advance of spring. With heavy showers and torrential rainfall, run-off and percolation (on pervious soil) increase and stream flow is rapidly augmented.

Effects of Geology and Topography.—There can be no question but that, next to intensity of rainfall, the geology and topography of a drainage area are the principal factors that control the proportion of rainfall that appears as stream flow. Fundamentally, the character of bed-rock of a drainage area is important. In Wisconsin, the rainfall conditions throughout the State are fairly constant, and the average is about 31 in. An investigation made a few years ago[30] showed that the average annual run-off from crystalline rock areas was 13.09 in.; from sandstone areas, 10.27 in.; and from limestone areas, 9.39 in. In some places, these areas are deeply covered with glacial drift (200 ft., or more), so that the bed-rock effect is modified considerably by pervious and impervious mantle deposits as well as by surface slopes and surface conditions, such as forests, cut-over land, cultivated land, swamps, lakes, etc. In fact, the conditions of the mantle deposits, soils, and subsoils lying over the bed-rocks may have as great an effect on run-off—and especially on the unformity of flow—as the bed-rock.

For example, the average yearly run-off of the Manistee River, at Sherman, Mich. (1904 to 1915, inclusive), was about 17.1 in., with an average rainfall of about 29.5 in., which is 1 or 2 in. less than that for the State of Wisconsin. The bed-rock is about one-half sandstone and one-half shales, and the high average annual flow, greater than that from the crystalline area in Wisconsin, is due to the deep sandy soil and subsoil over the bed-rock that rapidly absorbs rainfall and reduces evaporation and transpiration. On account of the storage in the great bed of sand, the flow, in cubic feet per second per square mile, is far more uniform, with an average of 1.26, a maximum of 3.89, and a minimum of 0.67.

---

[30] "The Effects of Bedrock on Runoff of Wisconsin Streams," by E. E. Foster, *Proceedings*, Eng. Soc. of Wisconsin, 1926, p. 162.

Any fragmentary mantle material that will remove the rain water promptly from the surface and store it at depths beyond the reach of evaporation will produce a similar effect on run-off. For example, the Deschutes River, of Oregon, has volcanic lava rock as its bed-rock. The upper part of this rock is cracked and fissured at the surface and perhaps to a depth of 1 000 ft., or more (its canyon in places is 2 000 ft. deep). It is covered by a comparatively thin and pervious soil over much of its area. From the limited data available the writer would judge that the average annual rainfall for the area probably does not exceed 12 in. The annual flow from this area averages about 8.75 in., and the flow, in cubic feet per second per square mile, has an average of 0.645, a 19-year maximum of 4.85, and a minimum of 0.38. It appears from the foregoing that the nature of the bed-rock and its pervious condition may have much to do with stream flow, but that pervious mantle deposits and fissured rock in the structure above the stream bed giving ample storage are the greatest factors in low floods and uniform flow of streams.

Surface and Soil Conditions.—Where pervious mantle deposits exist on a drainage area the disposition of the rainfall is greatly modified by the nature of the deposit and by surface conditions. A knowledge of the rainfall disposition has been of much importance in agriculture, and many experiments have been made to determine the evaporation and precolation through various classes and depths of soils and under various surface conditions. The writer has collected and analyzed the results of these experiments in another place.[31]

The points particularly noted[32] were the high evaporation and small percolation from sod, the high and maximum seepage through cultivated ground, and the high percolation and small evaporation from sand and pervious soils.

The run-off from any area is dependent on the pervious or impervious condition of the soil, the surface condition or covering, and the slope. Experiments were made in Wisconsin in 1929[33] on the run-off from various land areas. The highest average percentage of run-off found was less than 2% for forest covering, 20.1% for pastures, 24.1% for oat lands, 25.6% for corn land, and 21.5% for hay lands, the last three being probably somewhat reduced by the less average slope. With soil classed as sandy, the run-off in most cases was reduced below the average, undoubtedly by increased percolation. Here, again, the actual soil conditions are somewhat indefinite and the nature of the soil involved is not clearly discernible.

One of the most noteworthy examples of the increase in evaporation and transpiration (and possibly of percolation), and of the consequent reduction in run-off, is found in the change in the condition of Devils Lake, in North

Dakota (see Fig. 10). This lake, which has no apparent outlet and is very alkaline, had an area of about 115 sq. miles as determined by the U. S. Land Survey in 1883, and was at Elevation 1 435 (corrected elevation). In 1883, the surrounding country was opened to settlement. While the average annual rainfall in this area has been about 18 in. (see Fig. 11), the run-off (about 1 in. per annum) from the original prairie land surrounding the lake was sufficient to maintain it at about Elevation 1435 although it evidently fluctuated considerably with cycles of high and low rainfall years. (Note in Fig. 11 the reduction in elevation from 1867 to 1879). Since the land around the lake has been settled and cultivated, there has been a considerable decrease in run-off and a marked shrinkage in the height and area of the lake, evidently due to the opening of the land by cultivation. In 1927, its surface had fallen so far that it became divided into six or more smaller lakes and ponds, with an area of about 45 sq. miles and an elevation 21 ft. below that of 1883. At present (1932), the lake has fallen about 3 ft. more, or to Elevation 1 411, and has an area of approximately 40 sq. miles.[34]

FIG. 10.—DEVIL'S LAKE, NORTH DAKOTA.

A similar explanation will account for the drying up of certain springs, which has been attributed to deforestation. The probability of this assumption seems to be borne out by the data given in Table 13.[35] It will be noted from Table 13 that the daily consumption of water by most crops is given as several times greater than that of oak and fir trees. On the other hand, Harrington[35] estimates that on an average only 70% of the rainfall reaches the ground under a forest covering, and that 30% is re-evaporated from the trees and their foliage.

[35] Rept., Kansas State Board of Agriculture, December, 1889.

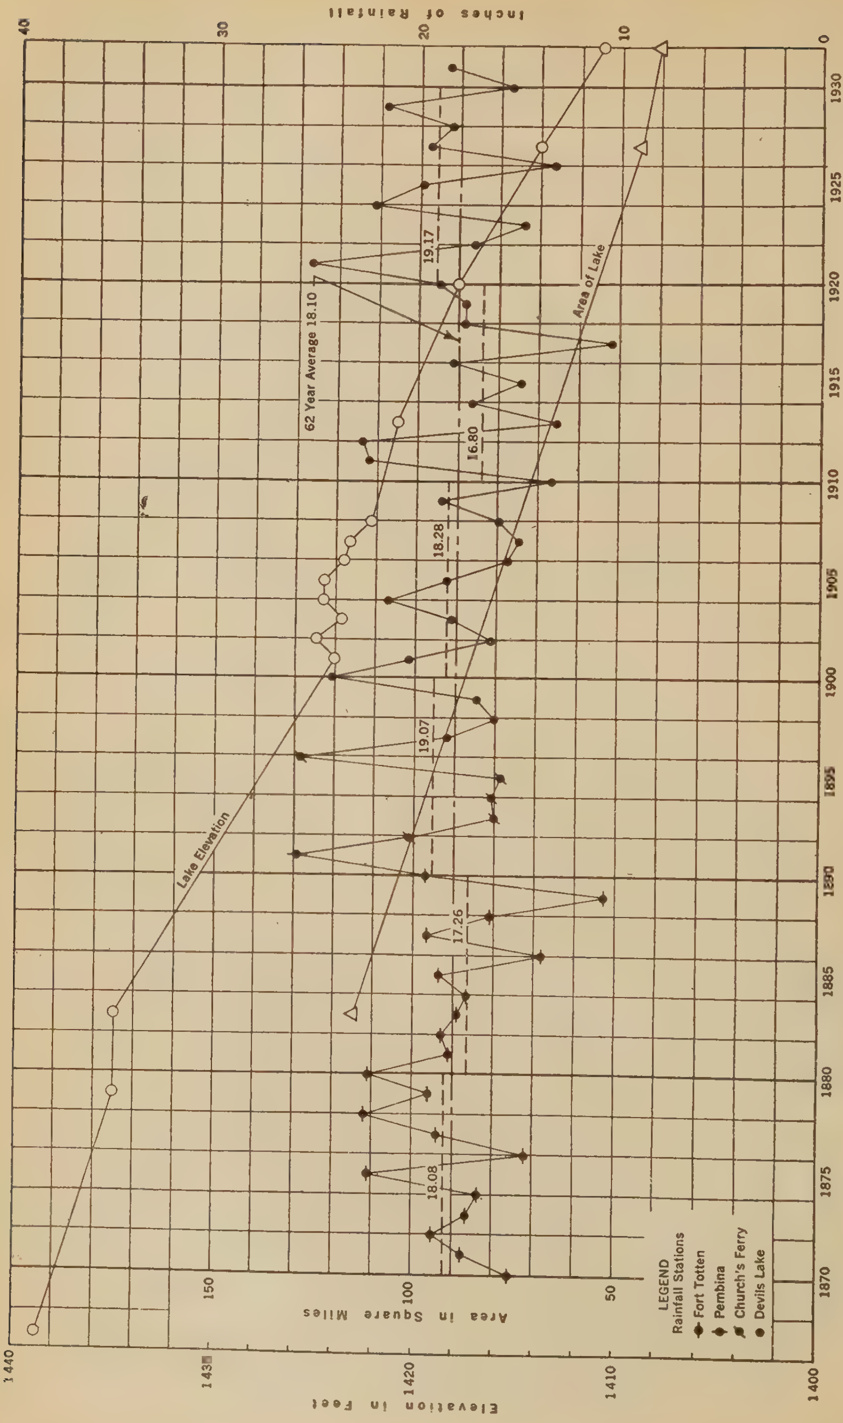

FIG. 11.—RAINFALL DATA AND LAKE LEVELS, DEVIL'S LAKE, NORTH DAKOTA.

TABLE 13.—DAILY CONSUMPTION OF WATER BY CROPS

Crops	Inches of Water		Crops	Inches of Water	
	Minimum	Maximum		Minimum	Maximum
Lucern grass	0.134	0.267	Wheat	0.106	0.110
Meadow grass	0.122	0.287	Rye	0.091	.....
Oats	0.140	0.193	Potatoes	0.038	0.055
Indian corn	0.110	1.570	Oak trees	0.030	0.038
Clover	0.140	.....	Fir trees	0.020	0.043
Vineyard	0.035	0.031			

The total use of water by trees compared with the evaporation from open water is given, as follows:

Transpiration	77%
Re-evaporation	61%
Forest soil evaporation	13%
Total percentage of open-water evaporation	151%

Woolny[35] has estimated the return of water to the atmosphere by various kinds of vegetation, compared with evaporation from open water, as given in Table 14.

TABLE 14.—PROPORTION OF WATER RETURNED TO ATMOSPHERE AS COMPARED WITH EVAPORATION FROM OPEN WATER

Vegetation covering	Proportion of water returned, percentage	Vegetation covering	Proportion of water returned, percentage
Sod	192	Mixed crops	144
Small grass	173	Bare soil	60
Forest	151		

Raphael Zon, Director of the Lake States Forest Experimental Station, considers[36] forests as the greatest evaporators of water, exceeding all other vegetable coverings. He quotes Otozky, a Russian physicist, as estimating the amount of transpiration from forests as nearly equal to annual precipitation, and is of the opinion that if the Atlantic plain and the Appalachian regions were deforested it would have a considerable influence on the humidity and rainfall of the Central States and prairie regions to the west. If this is true, it is difficult to see forests as conservers of waters for springs and stream flow. Tables 13 and 14 indicate entirely different conclusions and show that deforestation, followed with replacement by meadows and cultivated ground, will account for decreased run-off if such decrease were observed.

With the foregoing facts in mind, the writer believes that it is both logical and practical to outline the conditions favorable or necessary to assure certain conditions of run-off. This has been attempted for two extreme and opposite conditions, as follows:

---

[36] *Science*, Vol. 38, p. 71.

I.—Conditions Favorable to Maximum Annual Discharge and Equalized Stream Flow with a Given Rainfall:

(*a*) A fairly deep impervious basin underlying the drainage area from which no water can escape, except through the normal outlet of the stream.

(*b*) The basin in Condition (*a*) filled with pervious material, such as sand, sandstone, fractured volcanic or other cracked and fissured rocks (such rocks being covered at the surface with pervious soils), of such a nature and depth that the rains falling on the surface will sink rapidly into storage in the basin. The water must settle fast enough to avoid excessive surface evaporation and deep enough so that capillary attraction will not draw the stored water to the surface.

(*c*) The basin in Condition (*a*) with no surface storage on the drainage area.

(*d*) The basin in Condition (*a*) with only slight surface slope so that there will be no surface run-off, but rapid absorption into the pervious fill.

(*e*) A basin in which the area is entirely devoid of vegetation.

II.—Conditions Favorable to Torrential Flow and Maximum Variation in the Continuity of Flow with a Given Rainfall:

(*a*) An impervious basin, with steep channel and abrupt slopes to the divide; and,

(*b*) An impervious basin, with unobstructed channel and no mantle deposits or vegetation.

Under Conditions I, the rain falling on such a drainage area will sink rapidly into the soil and pervious underlying deposits, thus avoiding surface evaporation, and flow slowly toward the river channel, being sufficiently detained in storage to equalize the flow partly between the more or less periodic rain storms that occur over the area. Under Conditions II the rains will flow rapidly to the channel and through the river outlet in maximum floods followed by periods of entire cessation of channel flow.

In both the foregoing cases the distribution, intensity, and quantity of rainfall will have marked effect on the flow of the stream, but under the conditions of rainfall prevailing, one case will result in the best possible regulation with minimum floods and the other in maximum irregularity and maximum floods.

With these ideal conditions representing the extreme of regularity and irregularity in stream flow, almost any change in the conditions on these two areas will necessarily have opposite effects. In the first case, if the valley is covered with forests and vegetation, the pervious surface becomes more or less filled with roots and, therefore, less pervious. Evaporation will be increased, plant life will take from the supply, and flow will become more irregular and less in amount. In the second case, with the soil and detritus necessary for forest and vegetable growth, flow is obstructed, some storage is supplied, flood peaks will be reduced, and total discharge will be decreased.

Quantitative measurements of the actual effects of minor factors are frequently impossible although some effect may easily be demonstrable. Footprints across an impervious clay drainage area will fill with rain, reduce run-off by the amount so held, and will add to evaporation and possibly to seepage. Such results are positive although indistinguishable and unmeasurable as affecting stream flow.

Perhaps a more striking example of what would seem to be an important factor as affecting stream flow is shown in the apparent lack of effect on the drainage of large areas of land on the flood flow of the stream from the drainage area. Professors Woodward and Nagler[37] found, in the case of the Des Moines and Iowa Rivers, where a large portion of the drainage areas had been artifically drained, that during flood periods there were no significant changes in the behavior of the rivers that might be attributed to drainage.

The hydraulic engineer is perhaps more deeply interested in the question under discussion than are the men of almost any other profession. The conservation of water for water supply, water power, navigation, irrigation, etc., and the question of maximum floods in drainage and flood protection works are of the greatest importance. If water can be conserved, supplies increased, and floods prevented by any reasonable amount of forest covering, it is most important for him to know and to appreciate such facts.

Numerous investigations have been made by engineers interested in this question and unbiased in their opinion, and some of the results of such investigations are worthy of brief mention in this connection. Perhaps the most noteworthy of these studies was that of the late H. M. Chittenden, M. Am. Soc. C. E., already referred to by the authors.

In 1910, the writer endeavored to determine what influence, if any, the cutting of Wisconsin forests had had on the flow of Wisconsin streams.[38] No long-time measurements of stream flow were available, but from the gauge-height measurements of the U. S. Weather Bureau and the U. S. Army Engineers, the annual and progressive means of the annuals were found for the Wisconsin and Upper Mississippi Rivers.

The diagrams[39] clearly showed that high, mean, and low waters followed the quantity and distribution of the rainfall, and that there had been no marked change in the normal height of floods or in extreme low-water elevation.

In an investigation of the relation of forests to stream flow on the Tennessee and Cumberland Rivers, W. W. Harts, Brig.-Gen., U. S. A., M. Am. Soc. C. E., found[40] the relations of the height of high and low water at various periods during and following deforestation to be as shown in Table 15. He estimated that, in 1909, 60% of the drainage area of the Tennessee River was forested and that 20% of the area had been cleared in the preceding twenty-five years.

While these data (Table 15) might be taken to indicate a greater prevalence of extreme high and extreme low water during the earlier period when a greater proportion of forest covering existed on the drainage area, General Harts stated that the frequency and height of high water in both these rivers, as well as the duration of low water, followed the rule of precipitation closely enough during the period under observation to force the conclusions that this is the principal cause of the variation in these streams, and that "the introduction of forestry as an important factor in either direction is forced and illogical."

1889–1898...........	.....	.....	<5	.....	153.8
1879–1888...........	.....	.....	<5	.....	141.8

The investigations by General Harts were based on areas, in which deforestation had taken place through the cutting of timber through a considerable term of years.

Edward Burr, Col., Corps of Engineers U. S. A., (*Retired*), M. Am. Soc. C. E., investigated the result of reforestation in the Merrimac River Basin on the flow of that river.[41] In regard to the forest conditions, Colonel Burr states that (1) deforestation continued progressively from the earliest settlement to about 1860-70; (2) reforestation through natural processes progressed from 1870 to 1910 at a rate that has increased from 1880 to 1900, or later; and (3) forest areas were larger in 1910 than in 1860-1870 by as much as 25 to 30% of the entire basin. Perhaps better data (longer and more accurate) existed for this area as regards rainfall and stream flow than on any other for which similar studies have been made.

These studies, which seem to have been very thorough, included investigation of the relation of precipitation to high, mean, and low-water conditions. As in other studies, the irregularity of the consecutive annual occurrence of rainfall and run-off is so great that progressive averages are needed in order to ascertain tendencies in their relations, and, in these cases, 10-year progressive averages were used. Colonel Burr calls attention to the fact that his diagrams for total annual days of flood and for days of flood per inch of precipitation are approximately parallel to the precipitation diagram, indicating quite clearly that, when eccentricities are eliminated by averages over a period of 10 years or more, the duration of floods is dependent largely upon precipitation and that the duration of floods per inch of precipitation increases with the latter. Furthermore, he stated that the same characteristics are recognizable in regard to annual discharge, annual flood discharge, the percentage of annual discharge that runs off during flood stages, and the flood discharge per inch of precipitation. These characteristics are so marked that it is difficult if not impracticable to eliminate the influence of precipitation and to ascertain the existence and effect of any minor influence, such as variable forest conditions.

---

[41] See House Doc. No. 7, 62d Cong., First Session, May 23, 1910; also, *Engineering News*, Vol. 66, p. 100 *et seq.*

Colonel Burr found no evidence that deforestation or reforestation had modified the stream flow of the Merrimac River in any way. In this connection it seems pertinent to call attention to the fact that the highest floods that have ever been recorded on the Mississippi River, at St. Louis, Mo., were in 1785 and 1844, long before deforestation could have had any effect on the flow of that river.

These investigations and the data considered point to the conclusion that: (*a*) On large drainage areas any acts of man except the construction of relatively large storage reservoirs or extensive flood protection works, are so limited in extent that they can have little influence on the flow of streams; (*b*) stream flow follows rainfall; and (*c*), large floods are due to torrential rains, together with other physical and climatic conditions favorable to flood conditions. On small areas the cultivation of the land and the existence of extensive forests may have a considerable effect in decreasing the flow of small streams draining such areas, except that such effects are so small that they are likely to become insignificant and indeterminate on the flow of the main streams to which these small streams are tributary.

In general, there can be no doubt that all the factors described in this discussion have some effect on the disposition of rainfall, and, therefore, on run-off, but unless the effect is determinable and measurable it is theoretical and of little practical importance.

This subject has been before the public for many years and has been so surrounded by tradition and superstition that it has become greatly obscured. Extravagant claims as to the value of forests as a means of flood protection still persist. The lengthy discussion of this subject grows wearisome and would seem to be quite unnecessary were it not for its possible influence on legislation and the possibility of resulting large and useless (as far as flood protection is concerned) public expenditures. As late as February, 1929, the then Secretary of Agriculture, in his letter of transmittal to the President of the report on "Relations of Forestry to the Control of Floods in the Mississippi Valley," states:[42]

"Added study * * * shows that the forests of the Mississippi watershed were responsible for a reduction in the possible flood crest of nearly 15 inches.

---

[42] House Doc. No. 573, 70th Cong., Second Session, pp. III and IV.

Furthermore were all the forests of the Mississippi valley properly protected and managed in accordance with established forestry principles and practice a further reduction in possible flood crest of 55 inches would be possible."

He further states that this retaining effect would be equal to a reservoir storage of 46 000 000 acre-ft.

Such statements are so palpably absurd that they might be ignored were it not for the fact that they form the basis for a proposed expenditure of about $2 000 000 per year for protection and extension (?) of the forests in the Mississippi Basin.

RALPH R. RANDELL,[43] M. AM. SOC. C. E. (by letter).—On the only two water-sheds for which the matter has been investigated conclusively, it was found that: (1) Forests and brush substantially lessen stream flow at practically all seasons and stages, including flood, minimum, total, and average flows; and (2) forests and brush substantially lessen erosion.

These relationships have been established experimentally as to Area *B* of the Wagonwheel Gap experiment, in Colorado, and the Fish Creek water-shed, in Southern California. They were demonstrated during each of seven consecutive years in the case of the Wagonwheel Gap water-shed, and six in the case of Fish Creek, a total of thirteen years. No year showed contrary results with either water-shed.

The Colorado and Southern California water-sheds are widely different geographically, climatically, topographically, geologically, and in soil and vegetative cover, form of precipitation, and regimen of run-off. Especially significant is the fact that the winter precipitation on the Wagonwheel Gap water-shed falls in the form of snow, remains frozen on the ground all winter, and does not run off as stream flow until melted by the rising temperatures of the ensuing spring. The precipitation over the Fish Creek water-shed, on the other hand, falls as rain, and runs off immediately, except in so far as it evaporates or seeps underground temporarily.

The fact that all conclusive investigations show the foregoing relationships, even under such widely different circumstances and over such long periods of time, presumptively establishes that these relationships are of general application, and are not merely the result of any local or temporary peculiarities.

The same laws necessarily apply also to large water-sheds, as well as small ones; because large water-sheds are only combinations of small ones, and, therefore, must inevitably re-act to given influences, such as vegetative cover, in the same manner as the small ones of which they are composed.

The authors' contribution consists of the presentation and original analysis of the Fish Creek data, and a re-analysis of the Wagonwheel Gap data along lines somewhat different from those used by Messrs. Bates and Henry,[7] but with the same results. Their excellent paper should be of great benefit in directing attention to the real facts as to the influence of forests on stream flow. It is high time for engineers to discard, once and for all, the hoary fallacies that have been propagandized so widely and persistently during the last score or more of years. Especially important is it that they realize at last that all conclusive investigations show that forests and brush do not increase, but instead considerably lessen, both total water supply and low-season stream flow.

---

[43] Senior Engr., Federal Power Comm., Washington, D. C.

H. K. Barrows,[44] M. Am. Soc. C. E. (by letter).—A paper such as this is always welcome, adding as it does to the present information on a somewhat controversial subject.

The writer has studied the data presented from the viewpoint of water losses. It is obvious from Fig. 12 that on both the Wagonwheel Gap and Fish Creek drainage areas the yearly water losses have been decreased on the deforested or burned areas, and, hence, the run-off of these areas—which is the precipitation minus water losses—has been increased.

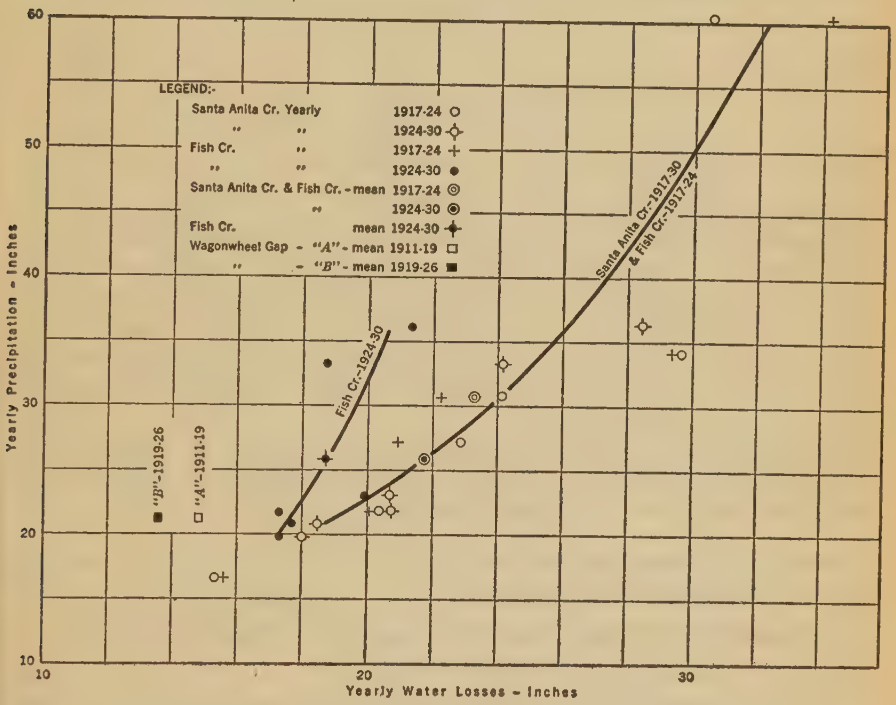

Fig. 12.—Comparison of Precipitation and Water Losses.

The lessening of water losses in respect to precipitation for the Southern California area is approximately as shown in Table 16.

The Wagonwheel Gap observations cover a much narrower range of precipitation (from about 17 to 24 in. yearly), but the period means for about 21 in. of rainfall, shown in Table 16, indicate fairly consistent results.

---

[44] Prof. of Hydr. Eng., Mass. Inst. Tech.; Cons. Engr., Boston, Mass.

It is evident that, in many cases, the lesser soil evaporation upon forested areas is more than offset by the demands of the forest for transpiration as well as its interception losses. The net result is that the forested area may show greater water losses and, hence, less yearly run-off than the deforested area, under conditions otherwise similar.

TABLE 16.—WATER LOSSES

Yearly precipitation, in inches (1)	WATER LOSSES, IN INCHES		Column (2) minus Column (3), in inches (4)	Ratio: Column (4) / Column (2) (5)
	Before deforestation (2)	After deforestation (3)		
SOUTHERN CALIFORNIA AREAS				
20	18	17+	1	0.05
30	24	20	4	0.17
40	27	21	6	0.22
COLORADO AREAS				
21	15	13.5	1.5	0.10

There is much misunderstanding on this matter by the layman, and many water-works officials in the Northeastern United States are devoting time and money to tree planting on drainage areas used for water supply, with the idea that they are thus increasing the supply, when they are more probably diminishing it. It may be worth while for other reasons, and perhaps a good investment, to adopt such programs of tree planting, but certainly as regards increasing the water supply the results are likely to be detrimental rather than helpful.

More and better information is needed on this subject in other sections of the country and, if possible, some experimental work in the study of comparative water losses on forested and open areas.

DONALD M. BAKER,[45] M. AM. SOC. C. E. (by letter).—The basic equation covering the disposition of precipitation is, as follows:

$$\text{Precipitation} = \text{Evaporation} + \text{Transpiration} + \text{Surficial Run-Off} + \text{Ground Storage}$$

In a closed water-shed, ground storage usually appears as stream flow. Any physical change on a water-shed affecting either the right or left-hand part of this equation will likewise affect the other part. Precipitation that reaches the ground surface might be increased by deforestation through the elimination of interception by tree or brush growth. The extent of this interception, however, is small, except in light showers or snowfall, and is probably balanced or equalized by greater evaporation from the ground surface.

Assuming little or no increase in precipitation, increase in surficial run-off, and ground storage must mean of necessity that evaporation and transpiration, or at least the algebraic sum of these two factors, are decreased.

---

[45] Cons. Engr., Los Angeles, Calif.

The observations in the two localities show the following results for the second period (depths of run-off over the water-shed being given in inches):

	Wagonwheel Gap, Area *B*	Fish Creek
Actual	7.261	6.95
Normal	6.306	5.40
Difference	0.955	1.55
Percentage increase over normal	15.2	28.7

Transpiration by forest or brush cover certainly is greater than 1.0 to 1.5 in.—the increase in stream flow due to deforestation—and it may reasonably be concluded that a considerable portion of the decrease in transpiration following the removal of trees and brush is counterbalanced by increased evaporation from a warmer soil.

The fact that the two localities at which the observations were made had widely differing climatic characteristics makes the analysis of results of greater than ordinary interest. Wagonwheel Gap is at a high elevation, has a low mean annual temperature of 34° Fahr., with a range of temperature from below zero to 80° Fahr., and a relatively uniform seasonal distribution of precipitation, a considerable portion of it in the form of snow. Surficial run-off in Wagonwheel Gap is small, except when the snow is melting, most of the stream flow coming from ground storage, which, however, is receiving constant replenishment. The percentage of run-off to precipitation under normal conditions was from 29 to 30, which was increased after deforestation to 34.3. Fish Creek drains a much lower area, has a much higher mean annual temperature, probably about 60° Fahr., with, however, a smaller annual range (from below 32° to 100° Fahr. at Mount Wilson) of precipitation concentrated in a few months. Surficial run-off is large and little of the stream flow comes from ground storage.

An analysis of the increase of the actual run-off over the normal for both Wagonwheel Gap, Area *B,* and Fish Creek, for the period after deforestation, as presented in Table 17, is of interest.

The increase in actual over normal run-off appears to follow a different rule on each water-shed. At Wagonwheel Gap during November, December, January, and February, when the weather is very cold and snow is probably accumulating, the proportionate increase is small, increasing during the months of melting snow. Again, in June, there is an actual decrease, while in July and August the increase is small. The increase from November to May is probably due to faster melting of the snow, which, in turn, is caused by higher temperatures due to lack of shade from forest cover, this rate of melting being accentuated as the general temperature increases during March, April, and May. In June, soil evaporation is in excess of decreased transpiration, but during July and August it does not exceed the saving made through lack of transpiration.

On Fish Creek, the situation is different. Precipitation ceases in April or May, and stream flow is entirely supplied from ground storage from that time until November or December. The increase during the rainy season, due to increased surficial run-off which, in turn, is due to lessened ground absorption, is small. Ground storage, which has accumulated during the rainy season, and which before deforestation supplied the brush cover and was transpired, now appears as stream flow.

TABLE 17.—ANALYSIS OF INCREASE IN ACTUAL RUN-OFF OVER NORMAL RUN-OFF AFTER DEFORESTATION

Total.....	7.261	6.306	0.955	15.2	6.95	5.40	1.55	28.6

A number of other things of interest are noted in the Fish Creek observations. In Tables 6 and 7 the effect of development within a short time of new cover on the reduction of maximum daily discharge, maximum peak discharge, and ratio of peak to daily discharge, indicates that it is grass and small vegetal cover that reduce surficial run-off, rather than heavy cover. The large increase in summer flow immediately after the fire on Fish Creek is probably due to the fact that increased erosion filled up the canyon with detritus and afforded an increased opportunity for ground storage, and that such fill was either eroded away, or through increased vegetation the water in storage was depleted through transpiration.

The analyses of the Wagonwheel Gap observations and of the Fish Creek data, as given in the paper, are distinct contributions to engineering literature, but broad conclusions cannot be drawn from them until much more quantitative data are obtained from other areas with different climatic, geological, and topographic characteristics.

Southern California has a marine type of climate. Moisture-laden air moves inland from the ocean, is forced to rise when it strikes the Sierra Madre Mountains, and in cooling, loses its moisture in the form of precipitation. The lack of summer rains is due to the fact that sufficient cooling does not occur during that period. Deforestation might be of value on a large scale under such climatic characteristics, provided that flood flows were not increased to a damaging extent, as it would not affect the source of supply for precipitation.

In a section with a continental type of precipitation, a considerable part of the moisture supply for precipitation comes from local evaporation and transpiration. Assuming an area several thousand square miles in extent (which had this type of precipitation source), to be deforested, the net evaporation plus transpiration would undoubtedly be reduced. Since it is the moisture received from these sources that goes to make up at least a part of the precipitation, the latter would likewise be reduced with a consequent reduction in surficial run-off and ground storage until a new state of equilibrium is established. As a specific example, consider conditions in the Southeastern States, where precipitation ranges from 50 to 70 in., stream flow from 20 to 40 in., and losses, which are made up of evaporation and transpiration, are constant at about 30 in., with none of the precipitation, or little of it, in the form of snow.

Deforestation would increase surficial run-off immediately following precipitation and undoubtedly would decrease ground storage. Whether the net change in surficial run-off plus ground storage would be plus or minus has not been established quantitatively, but the probabilities are that it would be a minus change. According to the observations in question, the change in evaporation plus transpiration would be minus, and since the equation of disposition of precipitation must balance, a reduction in precipitation undoubtedly would ensue. Since a large proportion of the precipitation during the growing season in this section is derived from local sources of moisture, the loss would be concentrated during this period, and might have a serious effect upon agriculture.

The foregoing discussion is given with a full realization that it is not based on any quantitative background, but with the purpose of showing that the conclusions reached from the observations in question cannot be accepted as general under all topographic, climatic, and geological conditions until many more quantitative data, collected under a wide variety of differing conditions, are available for analysis.

The methods used by the authors in the analysis of these observations are sound, and the conclusions drawn, as far as they apply to the water-sheds in question, are without question correct.

Ralph A. Smead,[46] Assoc. M. Am. Soc. C. E. (by letter).—The value of the analysis offered by the authors should be evident to any one who has given thought to the question of forests and stream flow. The writer was engaged with the U. S. Geological Survey some years ago in an earlier study of this problem under much less favorable conditions, and is doubly appreciative of the unusual opportunities for study offered by the areas analyzed in this paper. In 1911 and 1912, the Geological Survey conducted an investigation of a group of small water-sheds in the White Mountains of New Hampshire. As the field data covered only a little more than a year it was impossible to compare forested with deforested conditions on a single water-shed, and evidence had to be drawn from stream flow and precipitation records made simultaneously on the various water-sheds. Some of these water-sheds were covered with virgin forests, some were deforested by cutting, and some were denuded by forest fires. One great difficulty arose from the presence of numerous varying elements, other than forest cover, that might affect stream flow. Such elements include steepness of slope, exposure to sun and wind, size of water-shed, nature of soil, method of forest removal (whether by cutting or by fire), length of time since removal of forest, amount and nature of precipitation, etc. Even to estimate the effect on stream flow of such elements, and to determine the effect of forest cover alone, was far from a simple problem.

---

[46] Structural Engr., Los Angeles, Calif. Mr. Smead resigned on January 9, 1933.

In the case of the Wagonwheel Gap and Southern California areas, on the other hand, such varying elements either were not present or could be eliminated effectively, due to the fact that a single water-shed could be studied both with and without forest cover, and due also to the presence of a closely similar neighboring water-shed by means of which the variations of meteorological conditions from year to year could be taken into account in determining the "normal" discharges (as the authors term them) for the period after forest removal. Thus, from these unusually adaptable areas, data have been furnished, and an analysis has been made that presents convincing conclusions as to the actual effect of forests on stream flow.

The authors call attention to certain variations in the run-off relations between Areas *A* and *B* of the Wagonwheel Gap section, and take those variations into account, probably by as exact a method as is practicable, in computing the "normal" discharge from Area *B*. It would be of interest, however, to investigate the causes for those variations, with a view to a more accurate determination of the "normal" discharge. For instance, the lag of several days between the spring peak discharges of Areas *A* and *B* before deforestation is apparently due to the difference in exposure to sunshine on the two areas, and the consequent delay in snow melting on Area *B*. This is indicated by the difference in direction of the slopes, by the disappearance of the lag at the time of the rain storm of October 5, 1911, and by the decrease in the lag between these peaks after deforestation had given the sun better access to Area *B*. It is possible that the relationships between cloudiness (if records exist), and the variation in amount of the lag would further establish sun exposure as the cause of this lag. Cloudiness records, then, for the period subsequent to deforestation would make possible even more accurate determinations of the "normal" discharges for this period.

The writer appreciates the careful selection and orderly arrangement of data as presented in the various tabulations and charts in the paper. The authors have confined themselves to the essentials of the problem in the interests of clearness and simplicity. However, the writer believes that one more chart, similar to that of Fig. 7, but covering an entire year of Area *B* at Wagonwheel Gap, would be worth while. It would show clearly and at a glance, as only a chart can show, the distribution, for the entire year, of the increase in annual run-off. It would also show many other main features of the analysis.

George H. Cecil,[47] Esq. (by letter).—The subject of this paper is of vital importance to Southern California. Perhaps nowhere else in the world, and certainly nowhere else in the United States, is water of such vital importance. While it is necessary to life everywhere, in a semi-desert region it is essentially the determining factor in urban and industrial growth and agricultural development.

From the standpoint of the value of crop production, the Valley of Southern California is the richest agricultural area in the United States. Already, in some localities, agricultural development has progressed beyond the assured long-time average yield of the local water resources. Given a cheap and adequate supply, many more acres of land are susceptible of development.

The importation of water into Southern California is possible and, in the case of Los Angeles, with its supply furnished in part from the ranges of the Sierras, it is an accomplished fact. Further importations from the Colorado River are contemplated, and plans for furnishing this supply to the Metropolitan Area are well advanced. These imported waters, however, will be needed eventually for urban supply and, even if they were sufficiently bountiful to permit their use for agriculture, the cost is prohibitive for any except the most valuable lands.

The Federal Government, the State, counties, and many of the municipalities of the region combined expend annually well over $1 000 000 in the protection from fire of the mountain areas of the region. This vast sum is expended not for the purpose of protecting a commercial timber supply or, for the most part, even a growth of tree species. The cover is, in the main, chaparral—a word derived from the Spanish and signifying a growth of dwarf oak. Trees are found in the canyon bottoms, at the higher elevations, and scattered here and there along the ridges of the chaparral covered slopes. There is ample evidence that these tree species at some time in the past comprised a more appreciable part of the cover, but at the present time by far the greater part of these mountain water-sheds is covered with a heavy growth of brush species, so dense (except where recently destroyed by fire), as to be impenetrable except on foot, and even then with the greatest difficulty.

Protection is afforded the cover on these areas on the assumption that: (1) It is a conserver of water; (2) it controls erosion; (3) it retards flood run-off; and (4) recreational value would be impaired by its removal.

If the authors are correct in their conclusions, the agencies now expending such vast sums in protection might well pause and consider the justification of these expenditures. These conclusions are, that such protection is not justified from the standpoint of the first objective; that the second is of little importance; the third, while the relationship is admitted in part, is apparently not considered of sufficient importance to affect the conclusions; and the same is, by inference, the case with regard to recreation since, although this form of use is mentioned, the conclusion reached is that damage by fire does not interfere with the recreational use of an area. Certainly, if all the factors of the situation have been given proper consideration and the conclusions are correct, the Federal Government, State, and local agencies would not be justified in the expenditures they are now making.

---

[47] Executive Secy., Conservation Assoc. of Los Angeles County, Los Angeles, Calif.

There are several factors, however, that are important to the water user in Southern California, that have been overlooked entirely, and others that have not been given their proper value in arriving at a conclusion.

The mountain areas of Southern California perform their highest function in the production of a usable water supply for the municipalities and agricultural areas dependent upon them. Their use for recreation may be considered as of secondary importance.

The prime requisite in water production is that the water must be usable. This factor is of greater importance than the quantity produced, and is vastly more important than a minor increase in the sustained summer flow. Probably 95% of the water used for domestic and industrial purposes, outside the City of Los Angeles itself, is pumped, as is also upward of 80% of that used for irrigation. The reasons for this are several. The mountain canyons are steep and sites suitable for reservoirs are limited in number and expensive of development, precluding the storage of water except for municipal use where large communities are concerned. Further, the entire mountain area is faulted so badly and broken into blocks that the number of sites at which dams may be constructed safely, is few.

The mountain ranges of Southern California are the result of an upthrust of the earth's crust. The same, and subsequent, movements that gave birth to these mountain ranges and broke them into blocks, caused that part of the region lying between the foot of the upthrust and the Pacific Ocean to drop, thereby creating vast basins which, in the course of the ages, have been filled with detrital matter brought down from the mountains. This coastal plain is further characterized by the existence of lesser faults, resulting in the creation of numerous minor basins. In a study of the underground water of the South Coastal Basin, the State Division of Water Resources recognized no less than thirty-one such underground basins or reservoirs. The replenishment of these underground reservoirs which, as indicated, furnish the water supply for the major part of both urban and agricultural development, is of paramount importance.

In order that the water finding its way from the mountain areas on to the coastal plain may perform its maximum of use, as much of it as possible should percolate into the underground strata near the mouths of the canyons from which it issues. For years past, several communities, represented by the water companies supplying them, have spread the flood waters over the detrital cones by means of lateral ditches, increasing the wetted area and materially increasing percolation over that obtaining under natural conditions. The experience of these companies has proved beyond a doubt that, in order that water may be spread successfully and the maximum of percolation secured, it must be free of suspended matter. It is often necessary, during the first run-off of the season, to by-pass to the ocean a varying part of the flood flow. In the case of a water-shed that has been run over by fire, the quantity that must be by-passed because of the silt load is many times as great as that under normal conditions. It is admitted by the authors that the flood flows for the first few years after a fire carry an added quantity of silt.

Since repeated burning will be necessary to secure the increased flow that theoretically will result from destruction of the cover, this added silt load may be expected to continue until all erodable material has been carried off. Under such conditions, the water that will be lost to the ocean instead of being percolated into the gravels is many times the quantity that could possibly result from the added summer flow indicated. In fact, careful analysis of the estimated increase in the summer flow will show that although in percentage it reaches a startling figure, when reduced to actual run-off, in second-feet, it is almost negligible. Further, if a proper allowance is made for the solid material that will be carried at flood stage, and to some extent continuously, the increase in run-off for the winter or flood season will be decreased materially.

The quantity of eroded material carried by the floods from Fish Canyon is given little weight by the authors in arriving at their conclusions. The truth is that the detrital matter carried by Fish Creek, Sawpit Canyon, and Rogers Canyon, as an aftermath of the 1924 fire, not only damaged and destroyed a considerable area of agricultural land, but cost thousands of dollars for removal from highways and the railroad along the base of the mountains.

No flood-control dams have been constructed in these minor canyons. However, the Los Angeles County Flood Control District is spending approximately $25 000 000 in the construction of dams in other and more improtant water-sheds. The importance of water-shed cover to these engineering projects is freely recognized by engineers of the District. In a report on check dams dated May 22, 1931, its Chief Engineer, E. C. Eaton, M. Am. Soc. C. E., gives as one of his conclusions the following: "The most effective agent in both the regulation of débris and the reduction of flood peaks is the vegetation covering the watershed." Again, in a paper entitled "The Fire Problem and Erosion Prevention in Relation to Flood Control—Los Angeles County Flood Control District," presented at the Rural Fire Institute in February, 1931, Mr. Eaton states:

> "I have no figures on what fire prevention costs per year per square mile of watershed, but damages from débris deposits after fires, followed by only moderate storms, commonly run from $25 000 to $50 000 per square mile, and protective measures run anywhere from $2 000 to $20 000 per square mile. It is certain that prevention is much the cheaper."

In fact, the deductions made by Messrs. Hoyt and Troxell, if carried to their logical conclusion, would defeat the objectives sought in increased summer flow. With the destruction of the water-shed cover, the loose material would be carried eventually by the torrential rains down the steep canyons on to the valleys below. Even if the resulting damage could be ignored, as is suggested, the materials in which must be stored the water to produce the increased summer flow indicated, would themselves be carried away eventually. The result would be that the entire winter precipitation would immediately find its way to the valleys, and summer flow would be nil.

C. W. SOPP,[48] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper the authors discuss a question that is becoming of more and more importance, due to the desire of certain persons to increase the appropriations for forest protection, of others to reduce such appropriations as an economy measure, and also the belief of certain men interested in grazing lands that periodic burning of the water-shed cover is beneficial to forage growth. All these matters vitally interest public officials and engineers who have charge of procuring and distributing a supply of water for domestic use and irrigation.

The authors' deductions that the removal of the forest cover increases the total run-off is fundamentally correct. However, it is that part of the run-off rendered usable that interests engineers and water company officials. Measurements of run-off at the mouth of the canyon in some cases are not a true index of the water supply, but rather the measurement of the water that is diverted or that replenishes ground-water basins by percolation. The maximum run-off would naturally occur from absolutely bare water-sheds typical of certain desert mountains, but this is not desirable when considered from all economic standpoints. Water supply officials are concerned with the maximum quantity of water rendered usable and not with the total run-off.

The increased flood run-off should be modified by a factor, dependent on the silt load, that will reduce the measured flow to water content. This is of considerable importance as even after three years of settlement of the first year's samples, the authors found that the silt was about 45% of the total volume. During the flood the bulking would be greater.

There is a direct loss of flood run-off after denudation by fire or by deforestation through the impossibility of diverting the silt-laden waters directly on the lands. On a denuded water-shed the flashy run-off occurs during or immediately after precipitation and at a time when the lands are saturated from the rainfall and there is no need for irrigation. The side-hill erosion deposits a large quantity of débris in the stream beds, which is sufficient in most cases to transform a rocky stream bed into a broad sandy one. In the course of a number of years all this deposition is moved out by the stream, causing great difficulties at head-works. The material is moved continuously in the form of material in traction, which rapidly fills all diversion works. This necessitates a waste of water in diversion either because it is possible only to skim the surface of the water or because of the necessity of flushing the settling basins. The sluicing and skimming losses may more than offset the gain in run-off. Great difficulty was experienced in attempting to divert even the clear water of San Dimas Creek, in Southern California, for a year or two after its partial denudation in 1919. In another case of diversion of water for domestic supply the material carried in traction into the head-works was 1 cu yd per hour per sec-ft of water. The capacity of the settling basin was such that the water had to be turned out frequently and the basin sluiced. For these reasons, in the absence of storage, there is actually a direct loss of water for irrigation and domestic use.

---

[48] Asst. Engr., Pasadena Water Dept., Pasadena, Calif.

Reservoir storage is an absolute necessity to make usable the increased run-off from a denuded drainage area, but erosion causes a rapid loss of storage space. One-half the drainage area above one reservoir in Southern California was burned over, and the run-off of the following winter season, even though it was a year of sub-normal rainfall, caused a loss of 11% in storage space. The deposition in the reservoir was 65% of the total run-off during the first year. This appears an abnormally high percentage, but it is not out of line with the percentage obtained by the authors during the first year, as shown by their table of silt samples (Table 12).

On another Southern California stream a flood-control reservoir was constructed the fourth year after a water-shed was denuded by fire. The subsequent deposition behind the dam has caused a considerable loss of storage and has interfered with the operation of the outlet gates. This illustrates that even four years in this case was not enough for the recovery of the water-shed cover to prevent considerable erosion. In Southern California, as a rule, five years are required for complete recovery under the most favorable situation as regards soil and moisture supply. After each fire the fertility of the soil is reduced by the burning of the humus and by erosion. The succeeding vegetation is of a lower type, and this process, if continued, will leave water-sheds practically bare.

There is an admitted increase in the summer flow from denuded water-sheds. In semi-arid localities the moisture in the water-shed exists as capillary water in the soil on the slopes and as free or gravity water in the alluvium in the canyon and valley bottom-lands. Under these conditions the removal of the forest cover from the side slopes would not cause an increase in the summer run-off inasmuch as the total supply available is only capillary water, and the removal of the transpiration loss would not increase the stream flow. The removal of the forest cover from the bottom-lands, especially from those water-loving plants and trees that have their roots in free water, does reduce the transpiration loss and causes an increase in stream flow. It has long been the observation of foresters that the summer or low-water flow increases on water-sheds after fires, but springs on the slopes do not so increase. This beneficial increase in water supply could be obtained by deforesting the bottom-land growth without any increase in erosion from the side slopes and probably very little increase in erosion of bottom-lands. The increased non-flood run-off is dependent on storage in the soil cover, but such storage would only be temporary because the continued practice of deforestation would eventually cause the removal of the soil storage.

In addition to the loss of water under conditions of direct diversion from denuded water-sheds and of the loss of valuable storage space in reservoirs, there is an indirect loss where an influent silt-laden stream traverses ground-water basins. The silt content tends to seal the stream beds and to reduce the percolation and recharge of these basins.

The ultimate result of continued denudation by fire or deforestation is to cause all run-off to occur in flashy floods when there is little demand for direct diversion for irrigation. It will also result in the erosion of soil cover that forms the reservoir from which the increased summer flow occurs, thereby removing the one beneficial influence derived from such denudation. Furthermore, it necessitates large and cheap reservoir space to make the increased run-off usable, and such storage is rapidly lost. The water-sheds are destroyed for all uses other than maximum run-off. Such denudation and deforestation should not be permitted, except where maximum total run-off is the highest use for which a water-shed has been classified, and cheap reservoir space is available.

W. P. Rowe,[49] Assoc. M. Am. Soc. C. E. (by letter).—The major portion of the mountain drainage area, tributary to the South Coastal Basin of Southern California, is covered with chaparral or brush. The true timber area comprises the lesser portion at higher levels. This area is used almost exclusively for recreational purposes and is visited each year by more people than any National Park in America. These two classes of vegetation are rarely found intermingled, probably because the rains are not sufficient to support both. Either will predominate to the exclusion of the other. No person has ever advocated the destruction of the true timber area in order to increase or control the water supply; therefore, this class will be omitted from the discussion to follow, the writer's remarks being confined to the chaparral areas of Southern California.

The Forest Service of the U. S. Department of Agriculture classifies chaparral as "forest cover," and this classification leads to confusion among engineers in the true timber localities, who are not familiar with the distinction between the two. Until the last few years, the Forest Service referred even to the most insignificant brush fire as a "forest fire." The local newspapers were of great assistance in spreading this misleading information. There is as much difference between burning the chaparral and timber as between paring a finger-nail and cutting off a finger, except that burning of the timber is soon offset by a rapid growth of chaparral, whereas a finger can never be replaced.

Chaparral growth follows a regular and never-ending cycle: First, comes the natural growth; then, a fire, started by any number of causes, burns off the chaparral. Then, follows the dire prediction of the professional conservationists that the water-shed is destroyed and the water supply ruined. The chaparral starts to sprout as soon as the fire is quenched. Then occur the winter rains and a little more soil is added to the valley floor and considerable more water is added to the underground basins that regulate 95% of the local water supply. The chaparral growth is back to normal in a few years, and the cycle is complete. These cycles have been occurring since the first lightning flash struck the dry chaparral, and they have occurred at more frequent intervals since the first Indian discovered that a chaparral fire resulted in more abundant feed for game and that it made hunting easier.

Every stream water-shed consists of a series of still smaller water-sheds each of which is traversed by a drainage channel. These drainage or stream channels accumulate the surplus water reaching the water-shed and convey it to the main streams. They are usually bordered by water-loving plants and act as natural fire-breaks. The steep side hills are quickly drained of surplus water and the end of each summer generally finds a veritable tinder-box awaiting the least spark to start a typical chaparral fire. There is a school of thought in California, composed principally of old-time settlers, *ex*-forest rangers, and hydraulic engineers versed in local water supplies, which advocates periodic and systematic burning of small areas of the chaparral. By burning the canyon ridges at alternate periods of ten years, there would be not more than 50% denudation in any small water-shed and there would be less than 10% denudation of a major chaparral-covered water-shed at any one time. The period of ten years is used only for the sake of comparison. It might be found that either a shorter or a longer interval was better.

---

[49] Field Engr., San Bernardino; Engr., Coachella Val. County Water Dist., San Bernardino, Calif.

All the arguments that have been advanced against such a plan of controlled burning can be applied tenfold against the results of the present policy of protection. The fire that occurred in Ventura and Santa Barbara Counties in 1932 burned over entire water-sheds, and it is estimated that more than $100 000 was spent in trying to control it. A shift in the wind and accompanying fog extinguished this fire. It is estimated that more than $250 000 was spent in trying to control the San Gabriel fire in 1924, but a fog quenched this fire also.

The proposal of controlled burning of chaparral areas is not advanced as a measure for increasing the water supply, but as a simple method of fire protection to the recreational area and lessening, by at least 90%, the evils arising under the present system. The areas of most recent burning would be refuges for the game that is killed under the present system of maintaining areas of brush too thick and too extensive for quick evacuation in case of fire. The authors have exploded the theory that a burned-over area is destroyed as a water producer. It must not be overlooked, furthermore, that the very conditions that made it possible for the authors to draw their conclusions for chaparral-covered areas, were the result of a fire that did occur under the present policy.

W. C. LOWDERMILK,[50] ESQ. (by letter).—Questions are raised in this interesting paper concerning the influence of a mantle of forest vegetation, primarily on the yield of summer flow from water-sheds. The general conclusions, if tenable and if followed to logical ends, involve far-reaching consequences. The paper is one of the most important of recent contributions to the subject of forests and stream flow and requires scrutiny into methods used, analyses, and interpretation of data.

Conclusions are based on two water-shed studies, in diverse regions, under widely different climates. The Wagonwheel Gap area lies above an altitude of 9 000 ft in the snow belt of the Rocky Mountain region, within a continental climate in which annual precipitation is characterized by two approximately equal maxima, one as snow in winter, and the other as thunderstorms, or convectional storms, in summer. In this region the regimen of flow of the Rio Grande to which the Water-Sheds *A* and *B* are tributary, is well regulated, showing by channel conditions a minimum of sedimentation and irregularity of flow. The Southern California area, including Big Santa Anita and Fish Creek drainages, on the other hand, lies between elevations of 1 500 and 5 000 ft, within the coastal range of mountains, and within a typical Mediterranean climate in which precipitation is characterized by one maximum in winter and a long hot rainless summer. Regimens of stream flow show characteristic semi-arid type of irregularity with well developed outwash fans of coarse detrital material and extensive detrital filled basins. The Wagonwheel Gap study was conducted with great accuracy with respect to measurement of precipitation over water-sheds and environmental climatic factors and stream flow, whereas the Southern California study was an incident in stream gauging over a period of years along the mountain front of Southern California. No provision was made for an accurate determination of catch of water-sheds in question, nor of other climatic factors. Precipitation records of Mt. Wilson, an eminence on the west margin of the Big Santa Anita drainage area, are introduced with the assumption that precipitation fell at uniform ratios over the two drainages under observation. While the use of the unburned Big Santa Anita Water-Shed as an integrator of climatic factors is sound, it can serve legitimately only when total catch in precipitation is determined by measurements for the two drainages. Variation in rainfall from place to place within cyclonic disturbances in Southern California as shown in Table 18 is sufficient to impose a serious limitation upon the validity of the conclusions drawn from the study. Compare, for example, Items 8 and 9, using the catch of Big Santa Anita (Column (4)) as starting points. It will be noted that variations of 3 to 5 in. occur, in opposite directions.

---

* Water-year, or hydrologic year, October 1 to September 30.

The authors' description of vegetation for the Southern California area is inadequate in comparison with that of the Wagonwheel Gap study. The inadequacy of the description of vegetative cover is apparent in references to the paper compared with Fig. 13 and Table 19, in which data collected from twenty-five sample plots, under the direction of Mr. A. E. Wieslander, for the State Type Map, were generously supplied, and are summarized. The vegetative survey was made in 1928, four years following the burning of Fish Canyon. Dominant vegetation was mapped in sample plots shown on the map, and this accounts for absence of reference to subordinate occurrence of yucca and other species named by the authors. Riparian, or canyon-bottom, vegetation is not included in Table 19. Field sample plots are indicated by numbered circles in Fig. 13. Type lines were drawn on base U. S. Geological Survey quadrangle sheets from occupied points, checked by detailed sampling in plots.

TABLE 19.—COMPOSITION OF CHAPARRAL VEGETATION IN FISH AND BIG SANTA ANITA CANYONS

VEGETATION		COVERAGE (AVERAGE PERCENTAGE)*

* Coverage refers to dominant vegetation; subordinate species under dominant cover are not listed.

Apart from the description of vegetation on slopes, the paper by Messrs. Hoyt and Troxell is entirely misleading with respect to the condition of the canyon-bottom growth of alders, willows, sycamore, poplar, and oaks of the woodland type. It is stated by the authors that this growth was protected from the fire and so it was below the falls in Fish Canyon. Above the falls, however, the mesophytic sub-irrigated canyon-bottom growth was entirely killed, as checked by the writer and recorded by numerous photographs. This discrepancy of fact and description imposes another important limitation upon the conclusions regarding summer flow which will be referred to again.

Absence of treatment of geological structure and soil formation imposes another limitation upon the study as a corroboration of the findings in the

FIG. 13.—BIG SANTA ANITA AND FISH CREEK DRAINAGES, SHOWING COVERAGE BY VEGETATIVE TYPES AND LOCATION OF SAMPLE PLOTS OF 100 MILACRES, OR 0.1 ACRE EACH.

Wagonwheel Gap. Plotting of run-off against rainfall shows closer agreement between the catches measured in Big Santa Anita Canyon than at Mount Wilson, with a further indication that Big Santa Anita displays greater storage than Fish Creek under heavier intensity of rain when both areas were burned. The thin soils on the slopes of young mountains in Southern California offer comparatively small storage in comparison with deep soils of more gentle topography.

Before examining the principal question raised in this paper regarding effect of denudation on summer flow, it may be pointed out that the paper makes two important contributions: (1) It refutes certain important conclusions[51] of the late H. M. Chittenden, M. Am. Soc. C. E., cited in the paper; and (2) it indicates that erosion following denudation in Southern California is increased to a marked degree, to which experience and experiment fully attest.

A reference to the baneful influence of Colonel Chittenden's memorable paper is in place here. His conclusion that the "bed of humus" or litter of a forest floor is the chief agent of forest cover in absorption of precipitation is "an outstanding fallacy." Refutations of his conclusions in the discussion appended to his paper, require as much attention as his original paper. More recently the writer's studies[52] have shown that the capacity of a layer of forest litter to absorb water is of small importance in comparison with its function to maintain surface waters clear and the absorption capacity of underlying soil at its maximum. The mantle of soil in the final analysis is the absorbent of precipitation, not the forest. The forest cover, especially the litter which it produces, furnishes conditions which make for maximum possible water and erosion control on water-shed surfaces. It is curious that Colonel Chittenden's paper should continue to have its influence upon textbooks, writings, and opinions in this field of forests and stream flow when the late George Fillmore Swain, Past-President and Hon. M. Am. Soc. C. E.,

[51] "Forests and Reservoirs in Their Relation to Stream Flow, with Particular Reference to Navigable Rivers", by H. M. Chittenden, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXII (1909), p. 245.

[52] "Influence of Forest Litter on Run-Off, Percolation, and Erosion," by W. C. Lowdermilk, *Journal of Forestry*, Vol. XXVIII, No. 4, April, 1930.

has presented[53] a much more open-minded statement of the problem and deserves to rank in authority much higher than Colonel Chittenden.

The point of particular moment in the paper by Messrs. Hoyt and Troxell is the effect of deforestation by cutting in the Wagonwheel Gap and the denudation by fire in Fish Creek on summer flow, which is commonly said to be reduced by deforestation. The relative flow is small in comparison with the total annual stream discharge as may be seen in Table 20. The ratio of summer flow and the percentages of increase are within the accuracy of measurement of stream flow in the study in Southern California. The contribution becomes not of so much importance in indicating substantial increase in yield of water as in the new and conflicting information it presents concerning a widely accepted belief. From a study of the two areas it appears that the indicated increase in summer flow occurs from two different causes. In the case of Wagonwheel Gap the difference is really of minor importance but can be accounted for by difference in interception of summer rain. Interception of as much as 40% of rainfall has been measured. From 10 to 20% is a conservative figure for a dense high forest cover. Since the increase in summer flow following deforestation in Water-Shed *B* was 9%, this amount may be accounted for by reduced interception of summer rains.

Such a possibility is eliminated in the case of the Southern California study in the absence of summer rainfall. Quite another explanation is required. In another paper[54] the writer has set forth an analysis of factors affecting the yield of water from Southern California water-sheds. The salient points are that the mantle of vegetation subdivides into two distinct types as may be noted in Fig. 13, namely vegetation of drained slopes (chaparral) and vegetation of sub-irrigated canyon bottoms (riparian vegetation). Chaparral vegetation on drained slopes has at its disposal after the end of the rainy season only that supply of moisture retained by the soil of the root zone against the pull of gravity, namely, available moisture between water-holding capacity and wilting point. A fire in summer will not release water from such drained soils. In the succeeding spring re-growth of sprouting vegetation and the great coverage of volunteer annuals may be counted on to extract moisture during the long dry season approximately to the wilting point within the soil occupied by roots of sprouting plants and invaded by new growth. In the event that root zones are not as fully occupied the first season following a fire as prior to a fire an increase of run-off coefficients (other factors remaining identical), may be expected. Such increases, however, under the climatic conditions of Southern California are not to be counted on to an important extent.

Quite another situation obtains with the riparian or canyon-bottom vegetation. It is typically mesophytic vegetation, and has at its disposal during the long hot summer an abundant water supply in canyons of perennial flow, such as Fish Canyon. Large quantities of water are transpired into the air by this vegetation. Accordingly, when a fire kills this riparian vegetation transpiration draft is stopped and increased flow in the stream occurs. Not until the riparian vegetation has returned to its former transpiration capacity will the flow be returned to normal.

---

[53] "Conservation of Water by Storage", by George Fillmore Swain, Past-President and Hon. M. Am. Soc. C. E., Chester S. Lyman Lecture Series, Yale Univ. Press, 1914.

[54] "Studies of Factors Affecting Yield of Water from Watersheds in Southern California", by W. C. Lowdermilk, Proceedings Conference: Problems in Consumptive Use of Water and Conservation of Rainfall, Water Conservation Committee, Irrig. Div., Am. Soc. C. E., Los Angeles, 1930.

Since all riparian vegetation in Fish Creek above the falls (see Fig. 13) was killed in the fire of 1924, it is possible to account for the recorded increase of flow by reduction in transpiration losses of this type of vegetation along about 10 lin miles of main canyon and tributaries. For this reason the use of the Wagonwheel Gap experiment to support the findings from Southern California are brought into question as a scientific contribution.

This paper emphasizes the need of a thoroughly executed study in Southern California to answer satisfactorily the question raised as to method, and as to instrumentation and completeness in study of all factors. It must also be recognized that the question of transpiration loss on yield will not be the only basis for management of Southern California water-sheds for maximum beneficial yield of water. Storage in underground detrital-filled basins, control of flood discharges, and protection of flood-control reservoirs from sedimentation must enter into enlightened management of water-shed areas in Southern California.

RHODES E. RULE,[55] ASSOC. M. AM. SOC. C. E. (by letter).—The most important, and perhaps least understood, factor in the relation existing between vegetal cover and water supply is soil moisture storage. An idea prevails that significant quantities of moisture stored in the soil mantle during the rainy season are released later by slow drainage to surface streams, thus supporting the low-water flow of these streams. It is conceived that a dense brush or forest cover assists this process and thus acts as a conserver of water. Such misconception is due largely to mistaken ideas regarding the extent and velocity of soil moisture movement.

Many long-held concepts of soil moisture habit have fallen under the searching criticism of recent research workers. It is now definitely known that, in the absence of direct capillary connection with the water-table, movement of soil moisture under the influence of film forces is extremely slow. Other forces, probably closely related to the colloidal properties of a soil, tend to resist moisture movement and, as the moisture content of a soil decreases, the resultant force causing moisture migration becomes smaller and approaches zero at what Shaw[56] has termed the "normal moisture capacity" of a soil. At this point of static equilibrium the forces of adhesion and colloidal adsorption are great enough to prevent further movement and subsequent change of position must take place in the vapor phase. A wide range of moisture between this point and the hygroscopic coefficient, hitherto considered to be free to move under capillary forces, must remain in the soil until removed by evaporation or plant transpiration. Slow drainage is impossible after moisture in a soil has been reduced to this point.

---

[55] Civ. Engr. (Rule & Rule), Los Angeles, Calif.

[56] "The Normal Moisture Capacity of Soils," by C. F. Shaw, *Soil Science*, Vol. 23, p. 303.

In Southern California the native plant life draws heavily on the soil moisture supply during the long dry summers and at the beginning of the rainy season there is a considerable deficiency of moisture in the root zone. Many determinations have shown that the entire root zone is close to the wilting percentage of soil moisture before the first autumn rains. The soil moisture reservoir is empty; it must be filled before general percolation can penetrate below the root zone.

The first rain will penetrate the surface layers of soil and quickly fill them to field capacity to a depth dependent on the soil moisture deficiency, the lower portion of the root zone remaining dry. Immediately, evaporation and plant transpiration activities commence and draw on this accretion of moisture. There is little opportunity for slow capillary adjustment to take place within the root zone. In a relatively short time evapo-transpiration losses reduce the soil moisture content to the "normal moisture capacity," and capillary moisture movement ceases.

Succeeding rains, provided they occur soon enough and in sufficient magnitude, gradually push the moistened area downward, but in the period between rains evaporation and transpiration continue to take their toll. If the total rainfall is heavy enough the root zone may finally be filled to field capacity and when this condition is reached deep percolation can begin. It can probably be safely assumed that most of the water that penetrates to below the root zone will be returned in time to surface streams as ground-water seepage.

However, water that does not escape the root zone during the first quick gravitational drainage period following wetting has a negligible chance of ever passing out of reach of the plant roots. After gravitational movement has ceased, the ensuing capillary adjustment is so exceedingly slow and plant demands are so great that escape is practically impossible in any appreciable quantity. Where, as is the case in vast areas of mountain water-shed, the root zone comprises the total depth of the soil mantle, storage within the mantle for later release to streams is impossible except in negligible quantities.

Certainly all ground storage, aside from the permanent ground-water body, which can be classed as possible of future capture by human agencies is of a deep-seated nature, that is, below the root zone. It consists of water in transit under conditions of excessive application. It is water in excess of equilibrium capillary capacity that is working its way down to the water-table. (Equilibrium capillary capacity is the point of soil-moisture equilibrium at which the forces of gravity and capillarity are in exact balance. It is the limiting condition approached in a soil which has been saturated from the ground surface to the water-table and then permitted to drain for an indefinite period without losses by evaporation or transpiration. Thus, it is the limiting moisture content of that part of the lithosphere lying between the lower horizon of the root zone and the water-table in a region periodically subject to deep penetration of precipitation to below the root zone. No water can reach the water-table until the moisture contents of all higher levels of soil or rock along the course of percolation have been raised to equilibrium capillary capacity.)

Where the water-table is in bed-rock, this storage is the water contained in the soil below the root zone in excess of equilibrium capillary capacity, plus the water contained in rock joints in excess of the equilibrium capillary capacity of the joints. The writer's observations of mountain springs and in deep tunnels lead to the conclusion that in mountain water-sheds deep-seated open joints are the principal transmission channels for waters that have escaped the root zone. This is contrary to the opinion sometimes expressed that the moisture that eventually feeds surface streams must percolate along or above the surface of the bed-rock, thus being continually exposed to capture by tree and brush roots which extend to bed-rock. If it is true that most of the waters of deep percolation in mountain areas are to be found in open joints, it is apparent that cover conditions which serve to preserve the soil mantle have no effect on maintaining a storage reservoir for such waters. On the contrary, the soil mantle may serve to hinder rapid passage of the moisture into the open joints and, by intercepting moisture and retaining it for plant use, may decrease the total deep percolation.

Thus, assuming the soils to be the same, compare the effect of a deep mantle *versus* a shallow one. If the root zone extends to bed-rock in both cases, the root zone storage (field capacity) of a 10-ft soil mantle will be twice that of a 5-ft soil mantle, and it will require twice as much water to fill the 10-ft soil column if the moisture deficiencies of the two columns are proportional to their depths. In this case deep percolation would start sooner in the 5-ft soil mantle than in the 10-ft mantle. It will be found, in general, that the deep soil mantle will support a more luxuriant cover, due to the greater moisture storage ability of its deeper soil column. This greater storage ability for the benefit of wild growth causes a reduction in the residual quantity available for capture by Man.

Hydrological studies of valley and foothill sections in Southern California have led the writer to the following opinions:

(1) General deep percolation in these sections occurs only in years of exceptional rainfall. It occurs in spite of, rather than because of, the native cover.

(2) The native cover has adapted itself to its water supply and under usual conditions is able to convert nearly all moisture that penetrates the soil to its uses.

(3) If economically practical, an appreciable increment to ground-water storage can be made available by "debrushing" of waste lands on valley floors and outwash areas.

There remain to be explained certain water supplies that can not be accounted for by totaling the inflowing waters to closed basins. These additions to ground-water supply must result from the concentration of rain water in pools and streams and the resultant local deep percolation of rainfall as distinguished from general deep percolation.[57]

---

[57] "Water Supply from Rainfall on Valley Floors", by A. L. Sonderegger, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1242; see, also, discussion of this paper, p. 1269 *et seq.*

The observations on which the foregoing opinions are based, relate to valley and foothill sections of relatively small normal precipitation. Such sections are notably poor water yielders due to conditions of high evapo-transpiration losses relative to total precipitation. Data for the higher, more productive, water-shed areas are lacking. It is indicated, however, that consumptive use increases with an increase in precipitation. The evaporation opportunity becomes quantitatively greater and native cover more dense as precipitation increases. The statement previously made with reference to valley and foothill areas is probably likewise applicable here, namely, that deep percolation occurs in spite of, rather than because of, native cover. Much information is needed before definite concepts can be formed.

The only data available at present for studies of such productive water-shed areas are such as those presented by the authors in their timely and valuable paper. Resultant data of this nature are inadequate, however, for intelligent planning of water-shed control. The factors entering into the final results, as reflected by stream-flow measurements, are too many and too conflicting in their influences to permit final conclusions to be drawn as to how a particular water-shed or part of a water-shed should be managed.

In the final analysis the problem must be approached by hydrologic rather than hydrographic methods. The latter are valuable in checking the former, but are not sufficient in themselves. Evaluations of the separate factors of evapo-transpiration, deep percolation, soil moisture storage, and local surface run-off must be made for typical water-shed areas with characteristic cover types, before it will be possible to arrive at useful conclusions. Of course, these factorial evaluations must be supplemented by other studies of silting, damage to property, etc., but these considerations, although necessary, are apart from the present discussion.

In connection with the mention of the necessity for separate evaluations of consumptive use by different types of cover, the writer would like to have the authors discuss the subject of relative losses from the predominant chaparral cover of the Southern California water-sheds as distinguished from the water-loving growth found only in stream bottoms. From the writer's studies in a similar water-shed the possibility is suggested that the major portion of the increased summer flow after burning may have to be credited to reduction in consumptive use along the stream bottom, and that widespread burning of the chaparral cover may have had only slight effect on the low-water flow of the stream.

In conclusion, the writer wishes to urge that engineers and foresters, charged with the task of attacking the perplexing problems of water-shed management, make a thorough study of soil moisture behavior and the concepts of hydrology with respect to consumptive use of cover before committing themselves to definite policies.

ROBERT E. KENNEDY,[58] M. AM. SOC. C. E. (by letter).—Another rumor run to earth, one less alibi for procrustean argument! Heretofore, when it became necessary or desirable to explain more or less run-off, evaporation, or percolation as the case may be, it could be ascribed to the fact that Man had cut down the trees, drained the land, plowed up the sod, or done something to the water-shed. This paper contributes materially toward "nailing down" the bogy of deforestation.

---

[58] State Engr., Bismarck, N. Dak.

Devils Lake, in North Dakota, has become known extensively as a classic example of the assumption that the same conditions which result from deforestation have operated to reduce its elevation about 16 ft since the first immigration to the water-shed in the Eighties. In this case, it was not deforestation but the changing of the tight prairie sod to open porous wheat soil. The result is said to be the occurrence of less run-off into the lake by reason of the increased loss due to more subsoil percolation, more plant consumption, and to crop exportation.

Much investment—Federal, State, and private—will be impaired if the lake finally dries up. One of the chief arguments for an enormous and fantastic engineering project to obtain water from the Missouri River, 100 miles to the west and 265 ft higher in elevation, was the assumption that the lake would not come back to any extent by natural causes, as other no-outlet lakes have done, because the introduction of the plow to the water-shed had upset the delicate balance in meteorological factors affecting it.

However, it seems evident that whatever other factors may prevail those conditions usually resulting from deforestation do not apply here because apparently they produce more run-off rather than less. Moreover, it will be difficult to prove that the mere changing of the soil cover from one type of sod to another has any appreciable effect.

The gauge heights do not show it. The lake fell 11.3 ft in the 20 years from 1867 to 1887. This is 6¾ in. per year. From 1887 to October, 1932, a period of 45 years, it fell 16.4 ft, or at the rate of 4⅓ in. per year. During the first twenty years of the record, only climatic conditions could affect it. If human agencies have modified it since, the evidence must be sought elsewhere.

A readily computable factor frequently quoted is the quantity of water shipped out in farm products; but that is negligible. Eighteen inches of rain each year is the equivalent to 2 000 tons to the acre. Fifteen bushels of wheat to an acre contains only about 130 lb of water; but according to the report of the State Commissioner of Agriculture only about one-half the land was plowed in 1928 and 1929. This would mean that not more than 75 lb of water per acre existed in grain products and that not all of it was exported.

It might even be asserted with some display of statistics that somewhat more run-off rather than less could result from the introduction of cultivated crops. Be that as it may, there is probably little run-off at any time. The terrain is a pan and pot-hole, knob and kettle type of pleistocene glacial drift lying on cretaceous shale of the Pierre formation,[59] concerning which Professor Howard Simpson, of the University of North Dakota, states, "the region is almost unmarked by drainage lines save a few shallow winding coulees through which little or no water flows to-day."

---

[59] *Bulletin No. 598,* U. S. Geological Survey, p. 73.

There is a reported subsoil inflow of considerable but unmeasured quantity. If it has increased with the coming of the white man that development would tend to raise the lake rather than lower it; but there has been no report of a noticeable increase in the elevation of the ground-water table. No extensive land drainage projects have become necessary.

The lake has no doubt been dry or nearly so a number of times before. The same forces that filled it before are in all probability still operating without hindrance. It may be that, in the far distant future, great engineering works will be necessary to keep lake water out of the City of Devils Lake itself, now about 50 ft, or more, above the present water surface.

HERMAN STABLER,[60] M. AM. SOC. C. E. (by letter).—The American people are fond of hokum, and none is so prone to accept its dictates as scientists—seekers after truth—who delve in theories in the absence of substantial factual foundation. Perfect logic starting from false premises will lead to false conclusions. A consensus of scientific opinion in the United States thirty-five years ago on the subject of forests and stream flow is contained in the following excerpts from a report of a Committee (Messrs. Charles S. Sargent, Henry L. Abbott, A. Agassiz, William H. Brewer, Arnold Hague, Gifford Pinchot, and Wolcott Gibbs) of the National Academy of Sciences[61]:

> "The influence of forests upon climate, soil, and the flow of water in streams has attracted much attention during the past century; but while the general consensus of opinion among experts is that this influence is potent and beneficial, the absence of exact data extending over long periods of time, and the complex nature of the phenomena involved, render it necessary to base this conclusion rather upon general considerations than upon statistics."

With this introduction the Committee painted a picture of the natural regimen of streams "replaced by destructive floods in the spring, and by dry beds in the months when the irrigating flow is most needed" and of prosperous communities "depopulated" by reason of assumed destruction of forests on mountainous water-sheds of the arid regions of North America; declared that "unrestricted pasturing of sheep" must inevitably render "worthless for irrigation" streams rising in the Sierras and Southern Cascades; and concluded with the general opinion,

> "That, while forests probably do not increase the precipitation of moisture in any broad and general way, they are necessary to prevent destructive spring floods, and corresponding periods of low water in summer and autumn when the agriculture of a large part of Western North America is dependent upon irrigation."

It is little wonder that, with such backing of scientific opinion—even though based admittedly "rather upon general considerations than upon statistics," aided and abetted by the natural fondness of most people for trees and the undeniable value of forests as sources of wood and lumber—nationwide propaganda for forests as conservators of water and regulators of stream flow has taken firm hold on the imagination of the people and that it has become so firmly rooted in the popular mind as to be regarded as more or less axiomatic. Messrs. Hoyt and Troxell are to be congratulated for bringing before engineers statistical results in succinct form on the basis of which the volumes of propaganda, written and preached to the American public, may be adjudged. These statistical results, obtained in the very region chiefly considered by the Committee of the National Academy of Sciences, show that the Committee erred in assuming that loss of vegetative cover would produce dry beds of streams in summer and render them worthless for irrigation, and that claims heretofore made in behalf of forests on the basis of "general considerations" are clearly fallacious in some areas and, in the absence of statistical data to the contrary, must be assumed to be equally fallacious elsewhere.

---

[60] Chf., Conservation Branch, U. S. Geological Survey, Washington, D. C.

[61] Report of the Committee Appointed by the National Academy of Sciences upon the Inauguration of a Forest Policy for the Forested Lands of the United States, to the Secretary of the Interior, May 1, 1897, Washington, Govt. Printing Office, 1897.

The writer would be particularly interested to see the results of an experiment, such as that conducted at Wagonwheel Gap, undertaken in a humid region and under conditions most favorable to maintenance or betterment of low-water flow by vegetation. Such an experiment would substantially determine whether the principles set forth by Messrs. Hoyt and Troxell are universally applicable. Until such an experiment, conducted under trustworthy auspices, proves the contrary, one must assume universal applicability of these principles because of the wide diversity of conditions covered by their studies.

No one can be more interested than the hydraulic engineer in the actual facts of the case, and it is hoped that engineers will assist in accumulating a mass of statistical data relative to effects of vegetation on stream flow, that will furnish conclusive evidence applicable to a great variety of conditions. Engineers, however, are not by nature missionaries or propagandists. It will remain for some other group to educate the public. Is it too much to hope that those who have been most active in spreading doctrines now found to be fallacious will be equally zealous in disseminating the results of trustworthy statistical studies?

As a supplement to the studies of Messrs. Hoyt and Troxell mention should be made of another attempt to determine the effect of vegetation on run-off and erosion. This study was conducted on grass- and weed-covered slopes of the Wasatch Mountains, in Utah, and is reported by Mr. C. L. Forsling.[62]

The published results of the experiment show wide discordances in precipitation, run-off, and erosion for different observations. Amount and distribution of rain, intensity of precipitation, condition of surface as to moisture, temperature, marked differences in topographic and channel characteristics of the two areas, etc., all serve to obscure whatever influence vegetative changes may have exercised.

After extensive independent study of all results of the experiment the writer has concluded that summer storms, which produce most of the destructive run-off and erosion in the Wasatch region, offer the most instructive field for comparison with the results found by Messrs. Hoyt and Troxell. He, therefore, presents herewith a brief description of the conditions of the experiment and of the results of his study of the data relating to important summer rainfall.

---

[62] "A Study of the Influence of Herbaceous Plant Cover on Surface Run-Off and Soil Erosion in Relation to Grazing on the Wasatch Plateau, Utah," by C. L. Forsling, *Technical Bulletin No. 220,* U. S. Dept. of Agriculture, Washington, D. C., March, 1931.

Two adjacent areas of about 10 acres without perennial run-off were selected for study, Area *A* having a vegetative cover of 16% and Area *B*, a cover of 40 per cent. Collecting basins were constructed to catch all run-off and sediment, and rain-gauges were set up to measure precipitation amounting to about 30 in. per year. Observations were continuous from 1915 to 1929. Area *B* was maintained with 40% cover throughout the period by light grazing of cattle or sheep once or twice each summer. Area *A* had 16% cover through 1919, this being maintained by grazing as on Area *B*; increase to 40% was attained from 1920 to 1923 or 1924, by elimination of all grazing and the sowing of grass seed (wheatgrass and bromegrass) near the upper end of the area; and this higher value was maintained until the end of 1929, being kept down by grazing very lightly by cattle in September, 1925, and moderately by sheep once in late September or early October of 1927, 1928, and 1929.

Table 21 gives the statistical data as recorded by Forsling for July and August storms that produced run-off on both areas and that showed variation of not more than 25% in precipitation on the two areas.

By simple arithmetical operations, the progressive accumulations of precipitation, run-off, and sediment, the progressive accumulations of excess run-off and sediment from Area *A* over run-off and sediment on Area *B*, and the ratios (Area *A* to Area *B*) of progressive accumulated run-off, sediment, and sediment per inch of run-off, were determined from the data in Table 21 and are presented in Figs. 14, 15, and 16.

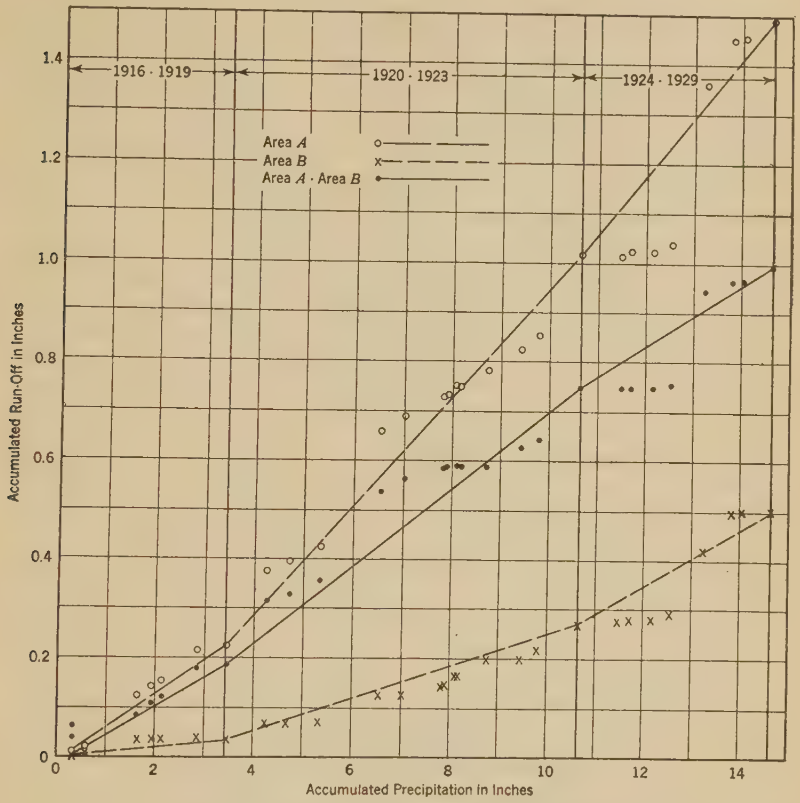

FIG. 14.—RUN-OFF—PRECIPITATION RELATIONS

Fig. 14 indicates that, relative to precipitation occurring in summer storms, Area *B* (vegetation constant) produced run-off at a higher rate in the second period (1920-1923) than in the first period (1916-1919), and at a still higher rate in the third period (1924-1929). Area *A* (vegetation variable) shows a similar trend, although the rate of run-off in the third period is very slightly greater than in the second. The excess of run-off from Area *A* over run-off from Area *B* shows very little change in rate. The inference to be drawn from these curves is that vegetational changes on Area *A* affected run-off but little—less, indeed, than other factors.

Fig. 15 indicates that, relative to precipitation occurring in summer storms, sediment was washed from Area *B* (vegetation constant) at a higher rate in the second and third periods than in the first, the rate being slightly less in the third period than in the second. Sediment was washed from Area *A* (vegetation variable) at practically the same rate in the first two periods, but at a slower rate in the third period. The excess of sediment washed from Area *A* over sediment washed from Area *B* was at a lower rate in the second period than in the first and at a lower rate in the third period than in the second. These trends strongly suggest that as vegetative cover on Area *A* was increased sediment removal was decreased. Doubt on this suggestion is cast by the fact that Area *B*, with constant vegetation, showed a greater rate of change than did Area *A* and that most of the decrease in excess of sediment (Area *A* over Area *B*) is due to the marked increase in sediment removal from Area *B* during the second and third periods.

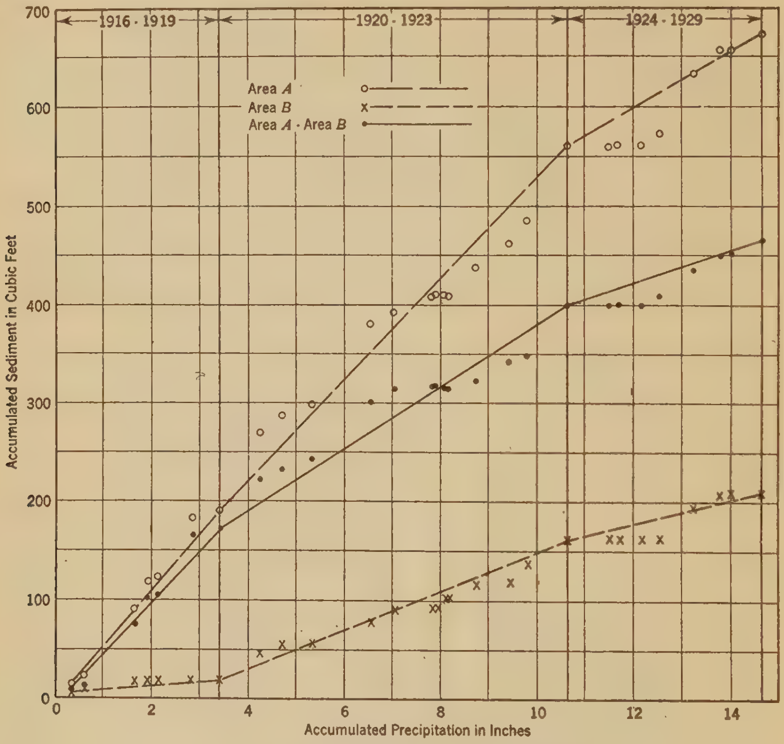

FIG. 15.—SEDIMENT—PRECIPITATION RELATIONS

Fig. 16, which deals only with relative results and, therefore, depends wholly on the reliability of Area *B* as a constant or "blank" for purposes of comparison, indicates, relative to precipitation occurring in summer storms, a striking reversal of trend both for ratios of run-off and for ratios of sediment removal. The ratio of sediment removal per inch of run-off, nearly constant at 1.7 during the first period, drops abruptly to another approximate constant, only about one-half as large, at the beginning of the second period, and changes but little from that point on to the end of the experiment. The third period shows, with respect to the second, a slight increase in the run-off ratio ($A:B$), a slight but somewhat greater increase in the sediment ratio ($A:B$), and a slight increase in the sediment ratio ($A:B$) per inch of run-off. These trends strongly suggest that elimination of grazing on Area *A* at the end of 1919 and the concurrent sowing of grass seed on the upper part of the area effected an immediate overwhelming change in the run-off and sediment trends, relative to Area *B*. Substantially the entire change seems to have occurred between July, 1919, and August, 1920. Yet Forsling's report states that "although grazing was discontinued in 1920, there was no change in the vegetation in that year." If this statement, surprising in view of the sowing of grass seed, can be accepted at face value one must look to the presence or absence of grazing animals rather than to any change in vegetation for the reversal of trends. This thought gains some strength from the observation that, in the third period, after grazing on Area *A* had been resumed in part, there is an indicated tendency toward return to conditions of the first period. However, bearing in mind that most of the trends are due to variations on the supposed constant Area *B* (which, as noted, is not a fixed quantity), all conclusions reached must be considered as tentative if not speculative.

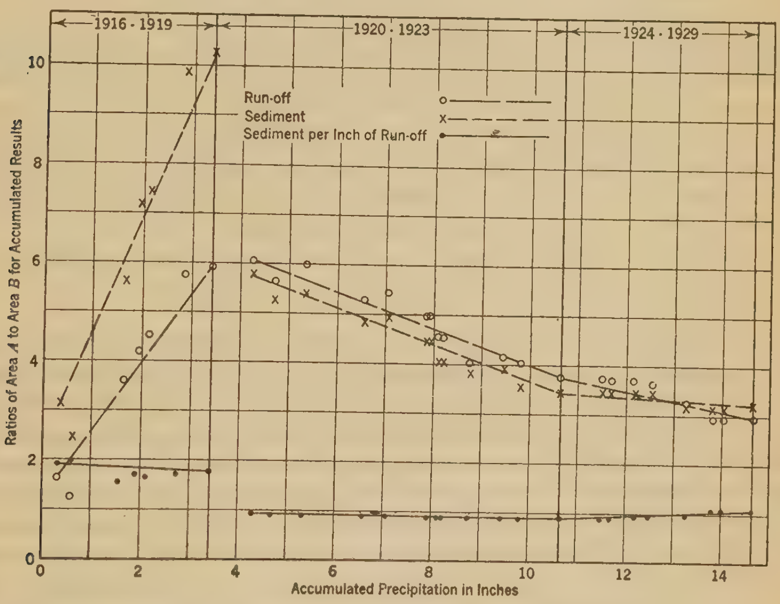

FIG. 16.—RELATION OF RATIOS TO PRECIPITATION

If the curves had been constructed with time elements instead of precipitation as abscissas, the slopes of all lines in the second period would be steeper and those in the third period flatter with reference to the slopes of lines in the first period. This follows directly from the record of 3.42 in. of rainfall in the four summers of the first period, 7.24 in. of precipitation in the four summers of the second period, and 3.99 in. of precipitation in the six summers of the third period.

The writer is inclined to draw the following tentative conclusions from his studies of the Wasatch Plateau experiment in the light of the study by Messrs. Hoyt and Troxell:

1.—On the steep grass and weed-covered mountain sides of the Wasatch Plateau, Utah, wide changes in vegetative cover and in grazing practices (*a*) produce little change in the rate of run-off from summer storms, slightly more run-off with more grazing and with less vegetation being indicated; and (*b*) affect notably the rate of sediment removal from summer storms, more erosion with more grazing and less vegetation being indicated.

2.—Under the conditions of soil, relief, and climate affecting the experimental areas, measures that will restore and maintain the maximum plant cover for grazing purposes will also insure adequate water-shed protection.

3.—A cover of grass and weeds, grazed under careful regulation, may afford protection to soil as satisfactorily and more profitably and deplete water supply less than a cover of useless brush. Relative effects of grass and weeds, brush, and trees on water supply and soil protection should be studied to afford a reliable guide in administration and use of lands.

4.—If wide variations in vegetative cover and grazing practices on steep mountain sides where the annual precipitation is about 30 in. produce changes in run-off and erosion no greater than indicated by the Wasatch Plateau experiment, neither variations artificially producible in the annual forage crop of about an ounce to the square yard on the relatively flat-lying and arid unreserved public domain (170 000 000 acres), nor the presence or absence of a stock population sufficient to harvest it, can affect appreciably problems of water supply or sedimentation of the arable lands of the West.

5.—The study, in general, tends to corroborate the conclusions reached by Messrs. Hoyt and Troxell and to extend their application.

H. S. GILMAN,[63] ESQ. (by letter).—It is quite possible that there are areas of water production and use, throughout the world, that will be greatly benefited by the findings and recommendations embodied in this paper. It is also possible that the authors' recommendations as to water-shed management will be adopted in field practice in an attempt to increase water yield. The result of actual field practice, if accompanied by close observations of all factors in water yield, may finally settle this old controversy of the beneficial or detrimental influence of forests upon stream flow and water yield. It is a surprising coincidence, however, that the observations upon which this discovery and findings were based, occurred on areas in Southern California, where, because of a combination of natural conditions, water-shed protection is popularly supported and practiced more intensively possibly than in any other area. Steep mountain slopes, a shattered rock formation, a layer of soil, a covering of scrub forest native to a semi-arid region, the year's rainfall occurring for the most part within a period of ninety days, few and costly reservoir facilities, a few miles of travel for the water from the mountains to the ocean—this briefly sets forth the water-producing machinery, and the authors recommend eliminating the vegetative cover and speeding up the run-off.

---

[63] Civ. Engr.; Member, California State Board of Forestry, San Dimas, Calif.

As manager of a mutual water company in Southern California for the past seventeen years, the writer has been in charge of diversion, production, and distribution of water for irrigation and domestic use, in an area of water production and use very similar to the areas of Santa Anita and Fish Canyons compared in this paper.

As is the case in most parts of Southern California, the annual water crop is produced from two sources—diversion of surface flows of the mountain canyons, and pumping from the alluvial basins beneath the plains and valleys. The surface gravity flows are unreliable in quantity as a source of supply, due to the seasonal variations in rainfall. The basins are more reliable as a constant source of supply, and act as an equalizing reservoir to carry over the years of deficient rainfall. For the past seventeen years, 20% of the Company's supply has come from gravity water and 80% has been pumped. Therefore, basin water, although higher in cost of production, is the most valuable because of its greater dependability.

Many water companies and agencies, recognizing the value of underground storage, have expended large sums of money in artificial works to increase percolation of storm waters over the débris cones at the mouths of the canyons for the purpose of recharging the basins.

In 1919, a forest fire denuded 50% of the slopes of the water-shed tributary to the area from which the Company produces its water, and the writer has direct knowledge of the effect of cover disturbance upon actual water production as opposed to a theoretical study which touches on one phase only, that of surface flow.

Water conditions in Southern California are such that maximum recovery of the annual precipitation must be made in both diversion of stream flows and through the pumping of underground waters. Any practical solution or suggestion as to water-shed or basin management that will increase the yield will be quickly applied to the problem by those in charge of water production. Arguments as to the benefits of denudation are as old as the hills themselves. The paper contributes nothing new as far as authentic data are concerned; and it overlooks, or sets aside as being of no consequence, certain factors that control water production, in all its phases, in this area. It is simply another instance of a plausible theory that will not stand the test of field practice.

The application of Mount Wilson rainfall data as a measure of precipitation upon both the Santa Anita and Fish Canyon areas to develop a formula for comparison of actual as against theoretical flows, in this scientific discussion, can scarcely be accepted as being sufficiently authentic to place in effect so radical a change in water-shed management as is recommended. Mountain rainfall records in Southern California are few and far between. Such as are available indicate great variations in seasonal storms and hourly intensity in the various areas. Variations up to 100% have been noted between stations ½ mile apart for various storms, and the picture of uniform precipitation in quantity and intensity over the areas reported, can be based only upon a wild assumption.

The U. S. Geological Survey records of stream flow in Southern California are full of examples of great variations per square mile of water-shed run-off between adjacent or distant drainage areas, where no cover disturbances have occurred. An intensive observation of actual rainfall "catch" upon these areas under discussion might have indicated a greater or lesser increase in yield, but under the circumstances the findings are valueless.

Besides questioning the authenticity of rainfall data used by the authors, other fundamental objections may be taken in their attempt to show a beneficial increased yield in production by reasons of denudation.

In the first place, the measurement of water over a weir is not the final measurement of water yield. In practical diversion and application to use, the condition and usability of the water, as well as the relation of mountain precipitation and run-off to basin recharge, are as important as the quantity. In the paper, while reference was made to the great percentages of solids in the water, apparently no correction of weir measurements was made, and everything flowing over was counted as water to show the beneficial increase. In practice of diversion and use, however, it is necessary for those in charge to make such corrections, not on paper, but physical corrections in the field, before the water can be used for spreading purposes or delivered and sold for use. Suspended matter in water prevents percolation into the basins and is objectionable in both irrigation and domestic use. The writer found that before the 1919 fire the stream cleared within two or three days after a storm so that it was usable for any purpose. For four years after the fire, suspended matter in the water and the stream-bed flow of sand and gravel, upset the old program of diversion and use to such an extent that any benefit in increased yield as indicated by Messrs. Hoyt and Troxell (including as it does the solids), was more than offset by necessary loss of water through the sluicing of settling basins before diversion could be made. The small increase in summer flow would be a high price to pay for the loss of percolation of winter waters in recharging the more important underground supplies.

That the data used by the authors permitted findings parallel to those for Wagonwheel Gap can only be laid to accident. If reliable data had been available and if the findings resulted as reported, the recommendations would still not be practicable in Southern California in the absence of recommendations as to erosion control, desilting, and a safe and economical method of denudation.

Considering their findings that, where flood control is a major problem of a drainage area, the maintenance of an undisturbed cover is desirable, it is difficult to visualize an area where population and irrigation demands are such that an increased yield of water is so imperative as to demand the drastic treatment of a water-shed by deliberate denudation, at the same time exposing itself, its people, and values to an increased flood threat.

Several counties in Southern California are spending many millions of dollars in the construction of engineering projects in an attempt to control or retard the normal and flood flows during the winter seasons. These projects, for the most part, are storage reservoirs in the mountains, usually constructed at high cost per acre-foot of storage. These reservoirs are expected to operate under conditions of normal water-shed cover conditions. It is questionable whether they would function under a denudation program of water-shed management, in the light of the authors' showing of a great percentage of increased run-off during the period of normal heavy flow. Furthermore, the economic life of a high-cost reservoir should be a matter for consideration in the light of the great increase of eroded material in the flow. The great percentage of increased yield during a period of heavy normal yield under these conditions, raises the question as to whether or not the increase is beneficial, while the lesser increased yield during the period of normal flow, or no flow, amounts to a surprisingly small quantity of actual water when computed in dollars and cents.

It is the writer's opinion that men in charge of actual water production and diversion of water in Southern California are as strongly in favor of water-shed protection as ever.

Charles H. Lee,[64] M. Am. Soc. C. E. (by letter).—The authors have presented a thorough and convincing analysis of the effects of deforestation by cutting, and denudation by fire, respectively, upon the stream flow of two small mountain water-sheds. They have done well in distinguishing between deforestation by cutting, and denudation by fire, because the destruction of the forest litter in the latter case constitutes a fundamental difference when considering the effect upon stream flow.

Although much impressed by the conclusions respecting these two water-sheds, the writer does not believe that the same conclusions can be extended indiscriminately to other water-sheds. Justification for this statement appears when it is found that differing causes produced similar results in the two water-sheds under consideration. For example, the writer recently examined precipitation data carefully observed during a 4-year period at eight stations in an area of mixed coniferous and deciduous forest trees, which indicate an average interception of rainfall during the summer months of 22 per cent. This percentage would fully account for the 12% increase in summer stream flow from the Wagonwheel Gap area after deforestation, even allowing for errors due to leaf drainage, etc., since this flow is derived principally from copious summer storms (Table 2). At Fish Creek, on the other hand, summer rainfall is practically zero, and stream flow is derived entirely from ground-water storage. The cause for the 475% average increase in summer stream flow, amounting to 65 acre-ft per annum (Table 9), can here be entirely accounted for by the burning of riparian vegetation which extended along the stream channel for fully ten miles (see Fig. 13). In other words, similar changes in stream flow resulted from entirely different causes. Further search might disclose other instances of apparent but not real agreement in the results for the two water-sheds.

---

[64] Cons. Hydr. Engr., San Francisco, Calif.

The writer is firmly of the opinion that correct general conclusions cannot be reached by taking into consideration forest and stream-flow data alone, but that all the hydrologic elements which influence stream flow must also be considered. Most of these elements are generally recognized, and may be briefly summarized as follows:

Precipitation upon a water-shed finds disposal from the area either as water-shed losses, stream flow, or sub-surface leakage. Water-shed losses consist of (*a*) evaporation from leaves and branches by interception (immediate); (*b*) evaporation from the soil (within 10 to 18 days after a storm); (*c*) evaporation from snow on the ground (within 2 to 6 months after a storm); (*d*) transpiration from vegetation (during growing season); and (*e*) evaporation from permanent water bodies, if any (continuous). Moisture that supplies transpiration from vegetation is derived from water temporarily absorbed by the soil, which remains within the root zone during the growing season and is in excess of the wilting coefficient of the soil.

Stream flow is derived from immediate surface run-off (largely flood flow), and from water permanently absorbed by the soil which penetrates below the zone of plant roots and joins ground-water storage at the water-table, reaching stream channels later as ground-water discharge (normal or low-water flow). Stream flow as measured at any point in the channel is a net quantity after deduction of channel losses, of which transpiration from riparian vegetation is usually the most important. Channel seepage losses may also be important where the channel is permeable and does not cut the water-table. Sub-surface leakage is a function of geological formation, and with an impermeable bed-rock is negligible.

This complete view of the problem shows that the various physical characteristics of water-sheds, such as meteorology, vegetation, topography, soils, and geology, all have an influence upon stream flow, and also that several physical processes are involved, among which are evaporation, transpiration, and absorption. Of these processes, evaporation and transpiration have and are receiving much attention, while little study has been given to absorption, either as to rate or total quantity.

Absorption may be defined as the processes by which water enters the earth. These processes include flow into sink holes, influent seepage, absorption by capillary films, hygroscopic absorption, and inflow of atmospheric water vapor. Absorption from precipitation has two aspects, its rate, which is directly related to immediate surface run-off and flood flow, and its total quantity, which is directly related to ground-water discharge which maintains normal and low-water flow.

Rate of Absorption.—What bearing does the rate of absorption have upon the relation of forests to immediate surface run-off? Just this, that the rate of absorption depends primarily upon the permeability of the soil, and in so far as forests increase soil permeability, they decrease immediate surface run-off, and to the extent that they decrease soil permeability they increase such run-off. Forests growing in highly permeable soils free from clay, such as dune sand, pumaceous volcanic deposits, coarse alluvium, sandy loams with less than 4% clay, and even pure silt, such as certain loess deposits, have little or no effect upon surface run-off. Forests growing upon impermeable soils and those which contain more than 4% of clay, however, have an important effect upon surface run-off by decreasing it as a result of increasing the permeability of the soil. They accomplish this through the agency of roots and forest litter by the following processes:

1.—Roots penetrate the ground where they open cracks in hard formations, such as rock, and permeate softer formations, such as clay beds, with root systems that expand the soil and ultimately give channels for the entrance of water.

2.—Forest litter promotes the growth of soil fauna, such as worms, bacteria, etc., which are very effective in opening up an impermeable soil.

3.—Forest litter provides a source for humus, which is of greatest importance in opening a clayey soil, not only mechanically by mingling with inorganic soil particles and separating them, but chemically by the production (in the process of decay) of solutions which, acting in conjunction with natural lime in the soil, facilitate flocculation or the assembling of clay particles into soil crumbs.

4.—Forest litter protects inorganic soil particles from disturbance by the impact of falling rain drops or by the movement of flowing sheet water, and thus prevents the clay from segregating out into suspension with a resultant sealing action upon a soil which, although originally more or less impervious, has been opened up by Processes 1 to 3. As an illustration, a suspension of colloidal clay will completely seal a column of clean medium beach sand having a weight one hundred times that of the clay.

5.—Forest litter protects the surface of the clayey soil from consolidation by preventing the puddling produced by hoofs of grazing animals, or the crusting and consolidation caused by shrinkage with exposure to the sun. The degree of consolidation of a clay soil has a very marked effect upon its permeability.

6.—Finally, forest litter prevents erosion with its destructive effects, not the least of which is the sealing of permeable channels and overflow areas in alluvial filled valleys which are normally the intake areas for the economically important ground-water resources of these valleys. It is to be noted, however, that brush or grass may be as effective as forest litter in preventing erosion.

Total Quantity Absorbed.—The quantity of absorption is dependent not only on soil permeability, but also on the amount and distribution of rainfall during the annual cycle, the storage capacity of the soil in the zone of aeration available for plant discharge, and the transpirational requirements of vegetation. Of the total quantity absorbed, a portion, which may be termed temporary absorption, reaches only the zone of aeration from which it is drawn back and escapes into the atmosphere by evaporation from moist soil or transpiration from vegetation. The remainder is permanent absorption which penetrates to the water-table and enters the zone of saturation. The latter is the ground-water storage which feeds stream flow.

Soil moisture research with partly saturated soils has shown conclusively that movement of water through capillary films not within the capillary fringe of a water-table is so slow that re-adjustments do not take place during the annual cycle. As a result, downward movement of water through the zone of aeration does not occur unless and until moisture content is at or above that at which free gravity drainage commences.

Tests made in brush-covered areas of sandy and gravelly soils on valley floors in Southern California to determine total deficiency in moisture content within the root zone (8 to 18 ft) at the end of the dry season, indicate values of from 8 to 14 in. The same tests show that, including current losses during the rainy season by soil evaporation and transpiration, approximately 19 in. of seasonal rainfall is necessary before any considerable quantity of water will penetrate beyond the root zone. Data obtained by the U. S. Geological Survey in Central California have been analyzed by the writer, which indicate that for uncultivated fine sandy silt loam soils with natural grass and weeds, a depth of approximately 12 in. is required. No data are known to be available for mountain water-sheds with either brush or forest. The steeper slopes tend to cause surface run-off prior to full satisfaction of field capacity, while the shallower soils tend to reduce the available storage capacity in the soil. It is believed that for most mountain water-sheds the limit is between 12 and 20 in.

It is thus apparent that in a semi-arid region a considerable quantity of rain must fall before permanent absorption can commence. In fact, in regions where the average rainfall is between 12 and 20 in., it is probable that accretions to ground-water storage through deep soils supporting natural vegetation occur only in wet years. It should be recognized, however, that in irrigated areas permanent absorption from rainfall occurs when considerably less than these quantities have fallen; also, that in shallow soils which are less in depth than normal root penetration and are underlaid by bed-rock, or other impervious formation, gravity water may begin to accumulate at the bottom of the soil column and a water-table may form when lesser aggregate quantities of rain had fallen. Under the latter conditions, which are not unusual for mountain water-sheds, ground-water contributions might be made to adjacent stream channels from the superficial soil cover, as distinguished from that yielded by cracks, joints, and fissures in the bed-rock. The quantity thus contributed is controlled by the length, slope, and permeability of the intervening soil path. In view of the very slow movement of sub-surface water, the amount of such contribution is limited to that yielded by the lower slopes, that from upper slopes being intercepted and transpired during the growing season by intervening vegetation.

Turning again to forests, the following applications can be made of these facts regarding the amount of absorption:

(*A*) Under arid conditions, vegetation has no effect upon ground-water contribution to the summer flow of streams, except that roots of riparian, or stream-border, vegetation discharge ground-water that enters or leaves surface channels as influent or effluent seepage, and thus decrease the flow.

(*B*) Under humid conditions, forests and other vegetation growing upon permeable soils decrease ground-water contribution to normal and low-water flow by transpiration, the quantity of the latter depending upon the requirements of the individual species. Deciduous forests consume more than grasses, but evergreens possibly not as much. Forests and brush growing upon soils containing appreciably more than 4% clay, however, offset this decrease by increasing the permeability of the soil, and in clayey soils may actually increase normal and low-water flow.

(*C*) Under semi-arid conditions (wet winter and dry summer), forests and other vegetation growing on deep soil decrease ground-water contributions to summer flow by transpiration as compared with bare soil. As precipitation and melting snow in such regions occur principally during the dormant period when transpiration is very slight, the decrease is less than the transpiration requirements of the species. The measure of the decrease is approximated by the quantity of soil moisture within the root zone and between field capacity and wilting coefficient. This follows from the fact that transpiration supplied by rain which falls during the growing season is largely an offset against evaporation from bare soil during the same period. The moisture depletion varies from 8 to 14 in. for brush on deep sandy soil in valleys. These limits would be less for shallow soils and for deep clayey soils, and are probably not out of line for forests in mountain water-sheds. For a season when rainfall plus current evaporation from bare soil exceeds these amounts during the period of replenishment of soil moisture, the substitution of forests for bare land would have no effect upon summer flow derived from ground-water.

Summarizing this discussion, and with particular reference to absorption:

1.—Forests decrease immediate surface run-off from precipitation: (*a*) By interception and evaporation from foliage, especially in summer; (*b*) by retarding the rate of melting snow lying on impermeable soil or rock; and (*c*) by increasing the permeability and, hence, the rate of absorption of soil containing more than approximately 4% of clay.

2.—Forests have no effect upon immediate surface run-off from precipitation or melting snow when growing upon highly permeable soil, nor under conditions of such long-continued or intense rainfall that the forest litter becomes saturated.

3.—Forests decrease summer stream flow derived from ground-water storage: (*a*) In humid regions by the full amount of seasonal transpiration on highly pervious soil areas and by lesser amounts on soils containing more than 4% clay to the extent that permeability is increased; and (*b*) in semi-arid regions by a portion of the transpiration not exceeding from 12 to 20 in., with smaller limits under various conditions of soil depth and permeability. This assumes that evaporation by interception offsets evaporation from bare soil without forest.

4.—Forests on clay soil may increase summer stream flow derived from ground-water storage by increasing soil permeability.

5.—Forests decrease total annual run-off as compared with that from bare soil, but as compared with brush or grass they decrease the run-off only when the total of forest transpiration and interception exceeds that of the brush or grass.

While these conclusions do not differ from those of the authors for the two small water-sheds studied, they indicate the errors that might result from too general an application.

W. G. Hoyt,[65] M. Am. Soc. C. E., and H. C. Troxell,[66] Assoc. M. Am. Soc. C. E. (by letter).—The earnest consideration given to this paper, as indicated by the numerous contributions submitted, is appreciated. It is also extremely gratifying that, with one or two exceptions, the discussions have either agreed with the conclusions and deductions of the writers or have contained constructive criticism.

Unfortunately, Mr. Bates looks upon the paper as an attack upon the forests and the forester instead of a contribution to the science of hydrology. He discusses soil, geology, meteorology, and "Nature's function" in an attempt to prove that the facts found in specific areas are not generally applicable. Reliable statistical information, however, collected under rigid scientific control in areas presenting widely different conditions, must be held to outweigh opinions such as he presents, no matter how firmly held or enthusiastically advocated.

No question has been raised by any member of the Society as to the method of analysis used, and no one has disputed the conclusions that on the two areas under consideration: (1) Forests and brush cover substantially lower stream flow at practically all seasons and all stages, including flood, minimum, and total flow; (2) forests and brush cover substantially lessen erosion where readily erodible material is available; and, (3) new vegetative growth exercises an effect similar to the original cover in retarding erosion, but without so detrimental an effect on annual run-off and summer low-water flow.

Messrs. Lowdermilk and Gilman deplore, as do the writers, the absence of precipitation records in the Southern California area. Hydraulic engineers will realize readily, however, that the method of analysis used is independent of rainfall records, but takes into account all normal differences in meteorological conditions that are reflected in run-off from the two areas.

Additional information concerning the climatic conditions and the geology would be most helpful in a search for the relative influence of causes contributing to the results. The lack of such information does not impose a serious limitation on the validity of the conclusions, nor does it cast doubt on the aforementioned facts.

---

[65] Hydr. Engr. (Prin.), Conservation Branch, U. S. Geological Survey, Washington, D. C.

[66] Asst. Hydr. Engr., Water Resources Branch, U. S. Geological Survey, Los Angeles, Calif.

However, the fact that Mr. Gilman apparently believes that the precipitation record for Mount Wilson had been used in computing the normal run-off of Fish Creek indicates that the method of determining the normal run-off, described in the paper, may not be fully understood by all readers.

Students of hydrology in Southern California have long known that there is not a simple direct relationship between run-off and rainfall. For example, a 2-in. rainfall, if concentrated within an hour, may cause flood run-off, but the same rainfall distributed over 24 hours would cause little if any run-off. For this reason, unless the intensity of the rainfall and its relation to run-off are known, the rainfall record is of little value in determining the normal run-off of Fish Creek.

The daily relationship of the discharge for Santa Anita and Fish Creeks was plotted for each day for the period prior to the fire (1917–1924). These points indicated a fairly well-defined, simple, direct relationship of the run-off from the two areas, as exemplified in the following tabulation, which records various simultaneous flows (in second-feet per square mile) that occurred during the winter months of January to March, 1917 to 1924:

Daily discharge, Santa Anita Creek	Daily discharge, Fish Creek	Daily discharge, Santa Anita Creek	Daily discharge, Fish Creek
40	82	2	2.6
20	37	1.0	1.2
10	16.5	0.5	0.58
5	7.4	0.2	0.21

The relationship was so well-defined for the period prior to the fire that there is good reason to believe that it would have been maintained for the period following the fire if the area had not been burned over. This relationship, wholly independent of records of precipitation, was used to compute the normal run-off from Fish Creek after the fire.

The rainfall records from Mount Wilson and Santa Anita Ranger Stations were included merely to show how little of the rainfall appeared as run-off at the gauging stations. For example, in Southern California, a seasonal rainfall of 20 in. produces, as a rule, a run-off of less than 2 in., and a seasonal rainfall of 30 in., generally less than 10 in.

Mr. Lowdermilk questions whether there is any relationship in rainfall for the drainage areas of Fish Creek and Santa Anita Creek and presents data showing the variation in seasonal rainfall at points ranging from less than 1 000 ft to more than 5 000 ft in altitude, and from less than 1 mile to more than 15 miles, from these drainage areas.

In Southern California many storms vary with the altitude; some affect only the higher altitudes, some produce rain only in the lower reaches, and others are general, giving much the same rainfall at all altitudes. Furthermore, storm rainfall varies from west to east and from east to west, depending on the direction from which the storm approaches. Thus, it would scarcely be expected that even an approach to uniformity in seasonal rainfall could be attained.

On Fig. 17 are plotted the relationships between storm rainfall for the period, 1917–1930, for Mount Wilson, for the San Gabriel power-house, near the mouth of Fish Creek, and for the Sierra Madre, just west of the mouth of Santa Anita Creek. For the lesser storms, Mount Wilson has sometimes more rainfall than the other stations and sometimes less, but as the storm rainfall increases, the relationship is better defined. In almost every storm the rainfall at the Sierra Madre, although generally greater than at the power-house, bore a relationship to that at Mount Wilson substantially parallel to that borne by the rainfall at the San Gabriel power-house. These comparisons should resolve Mr. Lowdermilk's doubt as to the general similarity of rainfall graphs for the two areas; but, after all, the most convincing evidence of rainfall relationship between these areas for which a direct record is meager, is found in the well-defined run-off relationship, for which the direct record is ample, continuous, and areally integrated.

The additional detailed information by Mr. Lowdermilk showing the composition of chaparral cover in Southern California is a welcome contribution to the discussion. It is regretted that the writers did not have access to unpublished Forest Service records, and that, therefore, their description of vegetation was incomplete, but after all the names of vegetative species and knowledge of their characteristics, like records of rainfall, are useful aids to interpretation of results but cannot change records of run-off.

Readers should realize that the Wagonwheel Gap experiments were extensive and exhaustive and that they cost tens of thousands of dollars. The Southern California study cost almost nothing, being incidental to routine stream gauging. The latter study lacked many of the details of rainfall, temperature, soil cover, and sediment observations of the former and, therefore, failed to afford as extensive a field for study of the relative effects of underlying causes. The effects of change in cover on run-off, however, were recorded as effectually in the Southern California area as in Colorado, and the major conclusions may be drawn with as much assurance on one area as on the other.

Facts or conclusions as to small specific areas have little value unless their application to other areas can be fairly well demonstrated. Mr. Bates presents the view that the Wagonwheel Gap and Southern California areas are so different from the greater proportion of forested areas in the United States that no conclusion generally applicable can be drawn from them.

In so far as the Wagonwheel Gap area is concerned the writers must dissent from this view. In 1922, Mr. Bates stated[67]:

> "It was, therefore, with a full realization of the need for experimental proof and in the hope of satisfying the most critical that in 1909 the Forest Service undertook to initiate a project which should produce results bearing particularly on the conditions typical of vast areas then included in national forests of the West."

[67] "Stream Flow Experiment at Wagonwheel Gap, Colorado; Preliminary Report on Termination of First Stage of Experiments," *Monthly Weather Review, Supplement 17*, p. 2.

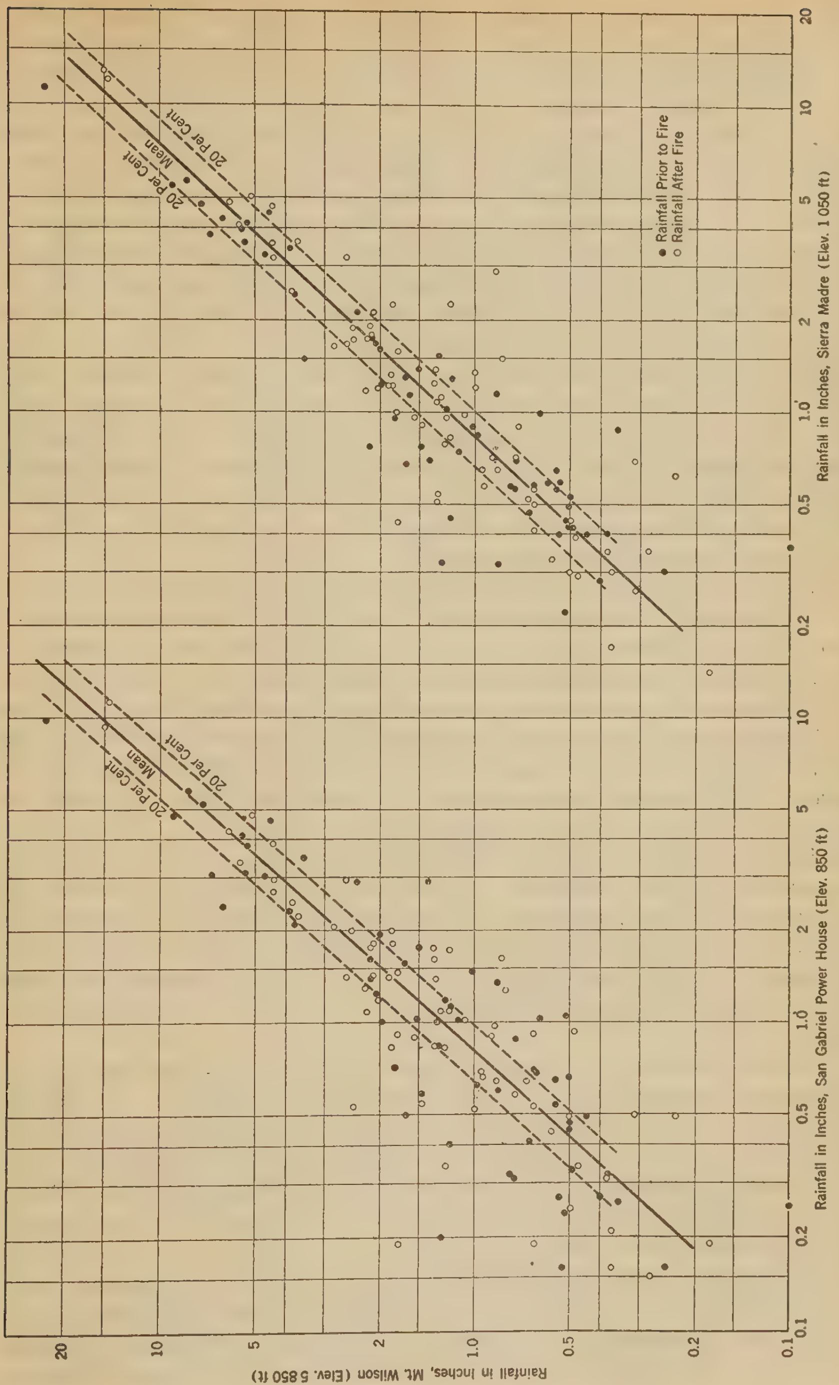

FIG. 17.—RELATION BETWEEN STORM RAINFALL; MOUNT WILSON, SAN GABRIEL POWER HOUSE, AND THE SIERRA MADRE.

In seeking areas where studies should be made, the following factors were considered by the Forest Service: Areas should be (1) contiguous; (2) small; (3) representative of a fair average for the National forests of the Rocky Mountain region; and (4) accessible. Credit for the discovery of such an area in Wagonwheel Gap is given to a Forest Assistant, and after the area had been visited by several Forest officials, including the Assistant Forester, its selection was approved. After close acquaintance with the area for more than twelve years Mr. Bates considered that "excellent judgment" had been used in its selection for the purpose of satisfying the most critical of the correctness of a preconceived conclusion. It scarcely seems fair to the public, when that conclusion is disproved in part, to suggest now that the area is extreme and not fairly representative.

Many of the other discussers take what seems to be a more rational attitude—that identical results in Colorado and California under such widely different circumstances constitute evidence of the probable universality of the conclusions, in the absence of trustworthy experiments to the contrary. All have stressed the desirability of additional exhaustive studies, and in that opinion the writers concur fully. Experiments in a humid area and on a fairly impervious soil are needed especially.

By processes of deduction, Messrs. Lowdermilk, Lee, and others, conclude that the increase in the summer flow from the denuded Colorado area resulted from decreased interception by the forest cover, and that the corresponding increase in the Southern California area resulted from decreased transpiration. No attempt was made in the paper to explain in detail the reasons for the increase, and, in the light of present knowledge, the writers do not believe that explanation is altogether possible or, if possible, that it greatly matters. All vegetation intercepts; all vegetation transpires. Removal of vegetation will diminish both interception and transpiration. If it is true that interception was in the ascendency in the Colorado area and that transpiration was in the ascendency in the Southern California area, that is just another of those differences in regional conditions that suggest the universality of conclusions that were identical for the two fields of experiment. The essential and undisputed fact still remains that with a diminution of the vegetative cover the annual flow and the low-water flow increased on both areas.

Additional studies have been made, however, and from these the writers believe that the deductions of Messrs. Lowdermilk and Lee are not entirely correct. To the best of their ability the writers have separated the run-off caused by summer storms from the ordinary non-storm run-off for three years prior to deforestation and for three years afterward. Some of the results of these studies are shown graphically in Figs. 18 to 21, inclusive; others are shown in Table 22.

The data in Table 22 fail to disclose that increase in summer storm run-off resulting from rainfall which should follow decrease in interception by reason of deforestation. The hydrographs in Figs. 18 to 21 are especially instructive in showing the increased non-storm summer flow after deforestation, a result that should logically follow decreased transpiration. It is clearly evident that there was more ground-water available to sustain summer run-off in the Wagonwheel Gap area after deforestation than before, and it is more than likely that both decreased interception and decreased transpiration contributed to this result, although the latter seems to have been the major cause.

TABLE 22.—STORM RUN-OFF AND RAINFALL, IN INCHES, JULY AND AUGUST, AT WAGONWHEEL GAP, COLORADO

Season	AREA *A*			AREA *B*			Ratio, storm run-off, Area *B* to Area *A*
	Rainfall	Storm run-off	Ratio	Rainfall	Storm run-off	Ratio	
(*a*) BEFORE DEFORESTATION OF AREA *B*							
1912	5.86	0.06441	0.010	5.81	0.05088	0.0088	0.790
1913	4.67	0.04415	0.0095	4.94	0.03902	0.0079	0.884
1914	7.10	0.09504	0.0134	7.47	0.05877	0.0079	0.618
(*b*) AFTER DEFORESTATION OF AREA *B*							
1920	3.32	0.03109	0.0094	2.74	0.01927	0.0070	0.620
1921	6.42	0.04653	0.0072	6.25	0.02758	0.0044	0.593
1922	5.40	0.07170	0.0133	4.88	0.06044	0.0124	0.844

Mr. Lowdermilk may also have gone too far in his assumption that all the gain in summer flow after the burning of the Southern California area resulted from decreased transpiration by canyon-bottom vegetation. Mr. Blaney's work in Coldwater Canyon showed that canyon-bottom vegetation during the 6-month period used 45 acre-in. per acre, or 238 acre-in. per mile of canyon. On the assumption that transpiration by riparian vegetation above the falls in Fish Creek Canyon proceeded before the fire at the rate per linear mile indicated for Coldwater Canyon, that such transpiration was wholly eliminated after the fire, and that there were no compensating water losses by reason of increased evaporation, it might be freely admitted that change in riparian vegetation could account for the entire recorded change in summer run-off. The first of these assumptions is speculative, however, and the others are untenable. Riparian vegetation would recover rather quickly from the effects of the fire, and if its destruction had caused increased summer flow this effect would soon be lost.

The increase in summer flow, however, was well sustained for several years, suggesting that no such close relationship existed between cause and effect here as was assumed by Mr. Lowdermilk. Moreover, there would be undoubted although quantitatively unknown increased evaporation to compensate in part for the effects of decreased transpiration by riparian vegetation. The continued maintenance of summer flow strongly suggests that these factors—transpiration and evaporation—were in fact compensating to a considerable degree. In the light of all the available facts, it seems that decreased transpiration was only one of several factors contributing to increased summer flow after the fire.

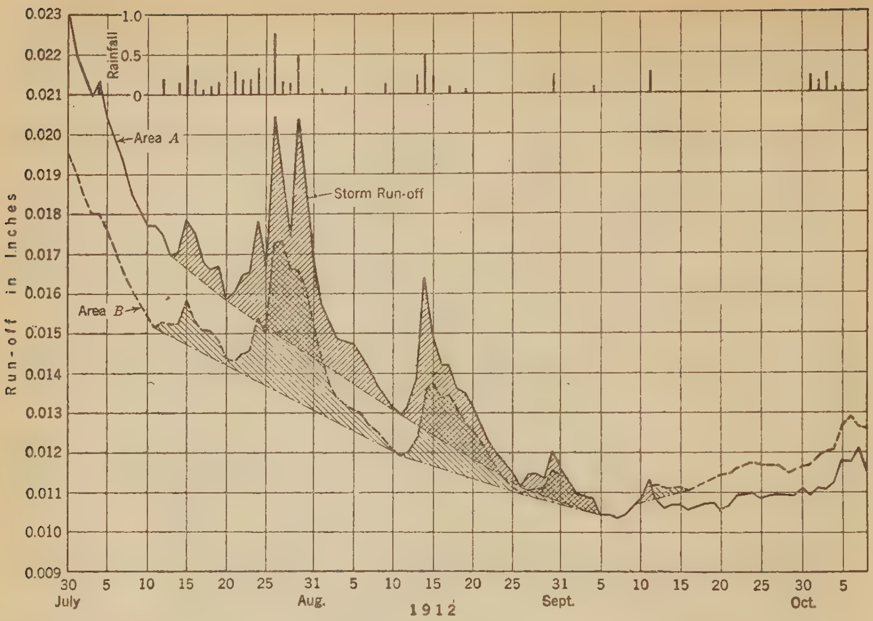

FIG. 18.—STORM RUN-OFF, WAGONWHEEL GAP, COLORADO, JULY TO OCTOBER, 1912 (BEFORE DEFORESTATION).

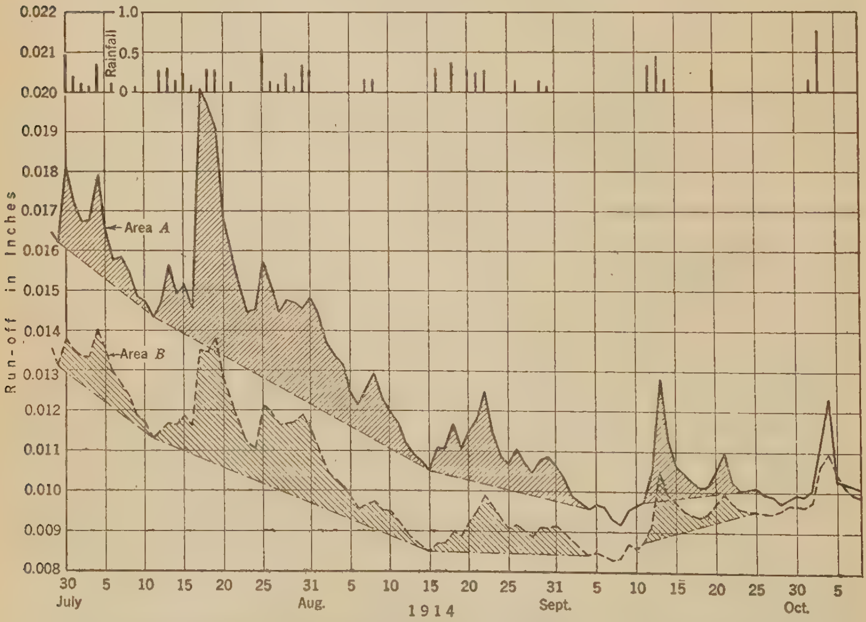

FIG. 19.—STORM RUN-OFF, WAGONWHEEL GAP, COLORADO, JULY TO OCTOBER, 1914 (BEFORE DEFORESTATION).

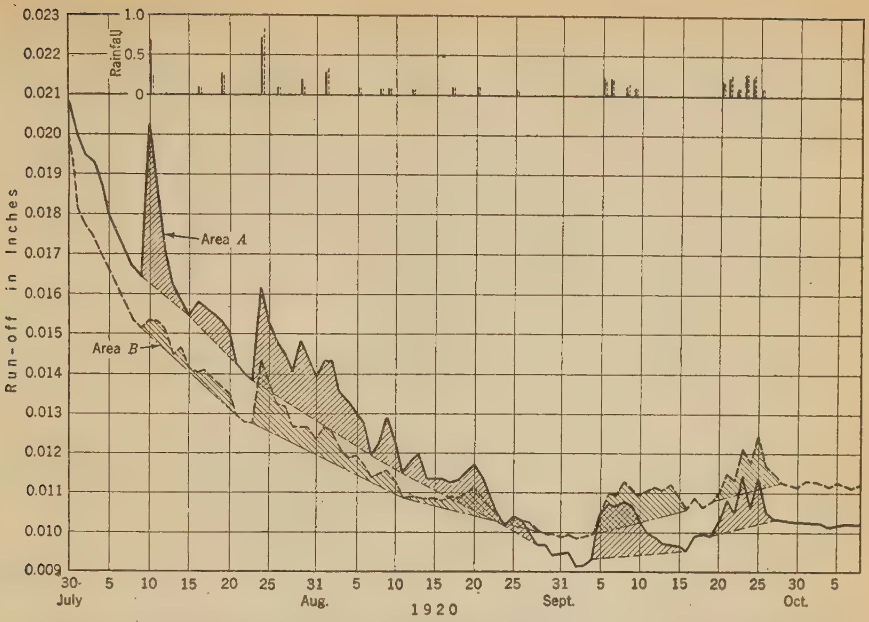

FIG. 20.—STORM RUN-OFF, WAGONWHEEL GAP, COLORADO, JULY TO OCTOBER, 1920 (AFTER DEFORESTATION OF AREA *B*).

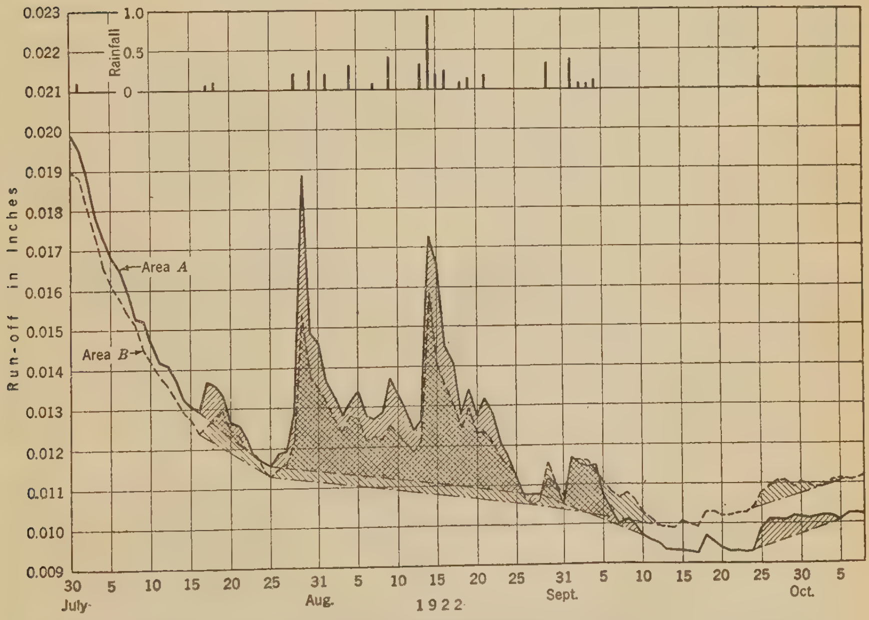

FIG. 21.—STORM RUN-OFF, WAGONWHEEL GAP, COLORADO, JULY TO OCTOBER, 1922 (AFTER DEFORESTATION OF AREA *B*).

Because of the many uncertainties involved the writers have refrained from attempting to distribute the source of the summer gain between the burned-over canyon-bottom plant life and the chaparral-covered canyon walls in Southern California, or between the interception losses, transpiration losses, and increased ground storage in the Wagonwheel Gap area.

Mr. Lee presents an excellent discussion of the part played by forest litter on run-off and absorption. Forest litter also forms the basis for the increased absorption in Mr. Sonderegger's "super-forestation." The recent experiments by Mr. Lowdermilk[68] have contributed to knowledge of the effect of litter on stream flow. In his discussion, Mr. Lowdermilk cites these experiments as a basis for the following statement:

> "The forest cover, especially the litter which it produces, furnishes conditions which make for maximum possible water and erosion control on watershed surfaces."

In so far as erosion is concerned the writers agree with this statement. They question, however, the use of the word, "water," in this broad conclusion if by "control" Mr. Lowdermilk implies that the presence of litter is reflected in an increased water yield, or increased low-water flow.

His studies show clearly that litter decreased direct run-off and, therefore, must have increased absorption. As Mr. Lee points out, however, part of the water passing into the ground is only "temporarily absorbed," being held in the zone of aeration, from which it escapes into the atmosphere by evaporation or transpiration from vegetation. The remainder is "permanently absorbed" penetrating to the water-table and entering the zone of saturation. This part is the ground-water storage that feeds stream flow. Mr. Lowdermilk fails to record the quantity of absorption that passed through the soil column in his tanks, and even if it had been so recorded it would not be indicative of Mr. Lee's "permanent absorption" under natural conditions, because the tanks were entirely artificial, in that they contained no vegetative cover to transpire what under natural conditions would have been "temporarily absorbed."

To have a litter-covered soil in Nature requires a canopy of brush or trees. As stated by many contributors, interception by and evaporation from such a canopy may range from 10 to 40% of the rainfall. Under natural conditions this interception might readily offset any increased absorption such as is inferred from results obtained in barren, artificially litter-covered tanks. Furthermore, the tanks used by Mr. Lowdermilk were set at a 30% slope, whereas in the Southern California area, as shown in Table 23, the slopes are much greater.

It will be seen from Table 23 that the major parts of both the Santa Anita Creek and Fish Creek areas have slopes exceeding 60 per cent. The slope at which the litter has the maximum effect on run-off was not determined by Mr. Lowdermilk, but it is possible that results from tanks with 30% slopes have little bearing on natural slopes exceeding 60 per cent.

---

[68] "Influence of Forest Litter on Run-Off, Percolation, and Erosion," by W. C. Lowdermilk, *Journal of Forestry,* Vol. 27, No. 4, April, 1930.

After all, the test of the effect of litter on low-water stream flow is not how much of the rainfall percolates into the root zone, but rather how much of the rainfall passes into the zone of saturation, which sustains stream flow during non-storm periods.

TABLE 23.—SLOPE OF SOIL AND CANYON WALLS OF SANTA ANITA AND FISH CREEK DRAINAGE AREAS

Slope	SANTA ANITA CREEK		FISH CREEK	
	Square miles	Percentage of drainage area	Square miles	Percentage of drainage area
Greater than 80%	1.5	14.3	0.5	7.7
From 80 to 60%	5.7	64.3	5.6	86.2
Less than 60%	3.3	31.4	0.4	6.1
Total	10.5	100	6.5	100

The field tests made by Messrs. H. F. Blaney and C. A. Taylor[69] on rainfall penetration on the valley floor present the results from actual rainfall in 1927–28, based on analyses of soil moisture. There was no direct run-off from any of the plots during the season involved. Table 24 shows the distribution of the rainfall.

TABLE 24.—EVAPORATION, TRANSPIRATION, AND RAINFALL PENETRATION IN SOUTHERN CALIFORNIA

Location		Soil	Crop	Dates	Rainfall, in inches	Evaporation and transpiration, in inches	Penetration below root zone, in inches	Stored in soil, in inches
Anaheim..	Plot A-1.	Hanford fine sandy loam	Clean	October 1, 1927 to April 15, 1928	12.39	6.0	1.5	4.9
	Plot A-2.	Hanford fine sandy loam	Cultivated grass	October 1, 1927 to April 15, 1928	12.39	12.0	0	0.4
Ontario...	Plot D-1.	Hanford sand underlaid by silt loam	Clean	October 1, 1927 to April 17, 1928	11.52	4.7	0	6.8
	Plot D-2.	Hanford sand underlaid by silt loam	Cultivated grass	October 1, 1927 to April 17, 1928	11.52	7.9	0	3.6
Ontario...	Plot E-1.	Hanford sand	Clean	October 1, 1927 to April 17, 1928	12.79	6.8	0	6.0
	Plot E-2.	Hanford sand	Cultivated grass	October 1, 1927 to April 17, 1928	12.79	9.6	0	3.2
Glen Avon Heights	Plot G-1.	Placentia loam	Clean	October 1, 1927 to April 13, 1928	12.18	8.1	0	4.1
	Plot G-2.	Placentia loam	Cultivated vetch	October 1, 1927 to April 13, 1928	12.18	10.5	0	1.7

In each of the tests noted in Table 24, more rainfall was stored in the clean cultivated plots than in those bearing vegetation. The depth of the root zone was from 6 to 11 ft, and the initial deficiency of soil moisture in the root zone ranged from 4.6 in. on Plot A-2 to 13.2 in. on Plots D-1 and D-2. As soon as the initial deficiency of soil moisture is overcome, rainfall penetrates below the root zone and becomes a contribution to ground-water.

---

[69] "Rainfall Penetration and Consumptive Use," by Harry F. Blaney, Assoc. M. Am. Soc. C. E., and C. A. Taylor, *Water Resources Bulletin 33*, California Dept. of Public Works, 1930.

The soil conditions, as so ably outlined by Messrs. Mead and Lee, would have a major effect on storm run-off and absorption. On soils of the more pervious material, forests have little effect on direct run-off. This is amply illustrated by Figs. 18 to 21, which show that the removal of the forest cover in the Wagonwheel Gap experiment did not perceptibly increase the storm run-off following summer rains.

"Super-forestation," as Mr. Sonderegger states, would "keep the water in the water-shed," but retarding storm run-off by means of plant life does not imply conservation of water. As Mr. Rule states, it results in "a reduction in the residual quantity available for capture by Man."

Under the climatic conditions existing in the Santa Ana River Valley and the Coastal Plain in California, according to Messrs. Blaney and Taylor:[70]

> "The results of the last three years' work on brush plots indicate that a seasonal precipitation of at least 19 inches is necessary before any material amount of water will penetrate below the brush root zone of the valley floors. A seasonal rainfall of less than 19 inches is usually consumed by the brush-covered area before the ground water receives any increment."

Messrs. Blaney and Taylor also show that for equal rainfall more of the rainfall passes below the root zone in bare soil than in soil covered with plant life and that deficiency of soil moisture is much less in bare soils than in brush-covered areas.

Recent excavation for roads in chaparral areas in Southern California has uncovered root systems that have extended as deep as 30 ft into shattered rock in search of water. Only during years of exceptional rainfall, such as 1921–22, could important accretions from rain be made to ground-water supplies in this region.

The writers are in harmony with Mr. Rule's valuable contribution showing the relation existing between vegetal cover and storage soil moisture. The facts brought out in several of the discussions tend to confirm Mr. Rule's suggestion that in so far as the Southern California area is concerned a large part, but not necessarily the major part, of the increased summer flow may be credited to reduction in the consumptive use of water by canyon-bottom vegetation. The writers stated, that "some of the alders and sycamores adjacent to the stream escaped burning." Mr. Lowdermilk declares that this statement is entirely misleading, as this condition prevailed only below the falls in Fish Canyon, while above the falls all canyon-bottom vegetation was killed. Apparently, less canyon-bottom vegetation escaped burning than was indicated to Mr. Lowdermilk by the word, "some."

The studies by Messrs. Blaney, Taylor, Nickle, and Young, as described by Mr. Blaney, are of outstanding value in showing the extent of water losses through transpiration by hydrophytic, or more properly phreatophytic, canyon-bottom vegetation. These studies show gains of more than 100% in summer flow through the elimination of transpiration losses in canyon bottoms having widths of only 30 to 50 ft. It seems apparent that considerable gains could be obtained through the reduction of similar losses now occurring in streams, such as the Santa Ana and others which meander for miles through wide brush and tree-covered areas. Pumping ground-water into conduits constructed across such areas, thus lowering the water-table below the root zone and reducing losses by evaporation and transpiration, may be economically sound in areas where water-rights are worth between $100 000 and $200 000 per sec-ft.

---

[70] "Rainfall Penetration and Consumptive Use of Water in Santa Ana River Valley and Coastal Plain," by H. F. Blaney, Assoc. M. Am. Soc. C. E., and C. A. Taylor, *Bulletin 33*, California Dept. of Public Works, 1930, p. 21.

Mr. Barrows touches lightly on one phase of the question which may be particularly applicable to New England and the North Atlantic region. Statements of foresters indicate that many water-sheds in this region have been heavily reforested with the sole idea of increasing water supply for municipal use. As Mr. Barrows states, and as the experiments clearly indicate, "it may be worth while for other reasons, * * *, but certainly as regards increasing the water supply the results are likely to be detrimental rather than helpful."

Mr. Baker believes that the "superficial run-off + ground storage" would be a "minus" after deforestation, and, consequently, that "precipitation" in his basic formula would be reduced. Here, again, the assumption is made that increased direct run-off necessarily connotates reduction of ground-water storage. It is an important fact that on the Wagonwheel Gap area the normal flood run-off was held temporarily as ground-water. The flood run-off increased after deforestation; consequently, more water must have entered the soil column after deforestation. The work of Messrs. Blaney, Taylor, and their associates in Southern California, already referred to, seems to substantiate this point.

Mr. Baker apparently accepts the conclusion as sound for areas having a "marine type" of precipitation, but raises a question as to the possible detrimental effect of deforestation of several thousand square miles having a "continental type" of precipitation.

The effect of plant life on precipitation is still a debatable question, to which there seems to be no definite answer. It appears unlikely, however, that the loss, if any, in the "continental type" of rainfall due to a change in vegetative cover from trees to smaller species would offset the gain in water supply. It would seem as logical to suppose that the present practice of irrigation on 30 000 sq miles of arid land in the West by changing the cover from the desert type to farm crops would have an effect upon precipitation as to suppose that a change in cover on several thousand square miles in the Southeast would have a serious effect upon agriculture. Incidentally, the Wagonwheel Gap area is probably as far removed from a "marine type" of climate as any other area in the United States that could be selected.

Comment seems unnecessary with respect to claims that deforestation has changed climate or that forestation increases precipitation. These and similar claims are believed to be incapable of either proof or disproof. Some assert that removal of the cedars of Lebanon brought destructive floods and resultant erosion[71], but according to the Bible long before those cedars were removed the greatest flood of the world took place and was the direct result of abnormal precipitation, as are the floods of to-day.

---

[71] Partnership of Wood and Water," by Hans Burger, *American Forests*, April, 1932, p. 147.

The studies by Messrs. Burr, Chittenden, Harts, Hazen, Mead, Stevens, and others already cited indicate, in a general way at least, that over broad areas no decreases in stream flow can be attributed to deforestation. To their conclusions may be added those recently reached in Ohio by C. E. Sherman, M. Am. Soc. C. E., who after a study[72] of run-off measurements made by Mr. D. S. Bates for the Ohio Canal Commission in 1825, when "not one-half of the 40 000 square miles of our Ohio territory is yet settled; more than five-sixths of it remains uncleared and uncultivated," concludes, in part, as follows:

> "The Ohio Canal Commission reports which give early stream records make surprising reading for those interested in the effect of forests on drought, for it is difficult to read them carefully without concluding that at many places in Ohio reforestation would have little effect in maintaining good stages of water during severe drought."

Mr. Lowdermilk states that the late Professor Swain, "deserves to rank in authority much higher than Colonel Chittenden." The writings and statements of both these distinguished and able engineers were made prior to the Wagonwheel Gap experiments. Professor Swain fully realized the need of tangible evidence when he discussed the late Colonel Chittenden's masterpiece in 1909. He states in his discussion[73] that,

> "In order to demonstrate quantitatively beyond peradventure the effect of forests, it would be necessary to have the same area under identical conditions in every respect, except that at one time it should be wooded and at another time deforested."

It is possible only to surmise to what extent the opinions of both these men would have been changed, if at all, had the results of the Wagonwheel Gap and Southern California experiments been available to them. Would they have ignored the records, or would they have changed their opinions to agree with the records? To the extent that the conclusions and deductions of both agree with facts as now known, they should be accepted; to the extent that they are shown to be fallacious, they should be ignored.

Mr. Smead mentions the investigations of 1911 and 1912 in the White Mountains which were carried on by the U. S. Geological Survey under the provisions of the Weeks Act. In these investigations ten nearly contiguous areas in New Hampshire were selected. No final report of the investigations has been prepared by the Geological Survey, but in a preliminary statement[74], the following conclusion was reached, based on comparisons made on two successive floods occurring on two of the ten streams during one spring period:

> "The results of the Burnt Brook-Shoal Pond Brook studies are held to show that throughout the White Mountains the removal of the forest growth must be expected to decrease the natural steadiness of dependent streams, during the spring months at least."

---

[72] "Ohio Stream Flow," Ohio State Univ. Studies, Vol. 1, No. 5, 1932, p. 164.

[73] *Transactions*, Am. Soc. C. E., Vol. LXII (1909), p. 365.

[74] Mimeograph report of thirty-one pages dated June 4, 1912, signed by George Otis Smith, Director.

On this conclusion rested largely the expenditure of several millions of dollars in the acquisition of National Forests in the East under the Weeks Act. Since the preliminary statement was issued considerable time and effort have been expended in a study of the original run-off records collected on the ten areas to determine whether it was possible to separate the effects of the inherent basin characteristics—soil, geology, shape, slope, and aspect—on the run-off from the effect of the vegetative cover.

To date this separation has not been possible, although apparently the inherent basin characteristics have more effect upon stream flow than the vegetative cover. In other words, observed differences may be the result of any one condition or combination of conditions, into which forest cover may not enter. This fact, which is also well supported by exhaustive studies referred to by Professor Mead and others and which is commonly accepted by all students of hydrology, renders studies without "control" substantially valueless. It is for this reason that the writers stress the value and importance of the type of studies carried on in Colorado and Southern California. In these areas changes from the normal are shown to be directly related to changes in the vegetative cover.

In all prior experiments, such as those mentioned by Mr. Smead, many described by Mr. Zon,[75] or the much quoted Swiss experiments,[76] it is impossible properly to ascribe reasons for noted differences in stream flow, because of a lack of "control." There is no doubt that further studies through the co-operative effort of the ecologist, forester, soil technologist, hydraulic engineer, and geologist, are necessary to determine the best type of vegetative cover for different types of soil, topography, and rainfall.

Such studies may well follow the method used at Wagonwheel Gap. In fact, in that area there is an excellent opportunity for an interested agency to study the effect of the new growth of aspens on stream flow as compared with the original cover, which consisted largely of conifers. The Utah experiment by Forsling referred to by Mr. Stabler was made along the lines adopted for the Wagonwheel Gap area. It was not wholly satisfactory, however, on account of the inability to hold an area in a semi-arid country uniform as to minor surface irregularities and vegetative cover. Still, as Mr. Stabler points out, the Forsling experiment tends to corroborate conclusions in the main paper and to extend their application. The type of experiment outlined by Mr. Blaney is satisfactory so long as it is conducted in rock-walled canyons having no ground-water inflow between the measuring sections. In areas where ground-water inflow takes place complications are introduced, which make it extremely difficult to determine losses resulting from vegetation. Controlled experiments on small plots, to which reference is made by Messrs. Bates and Lowdermilk, are unquestionably of value, but there is grave doubt as to their application to natural water-sheds in so far as water yield or net erosion is concerned.

---

[75] "Forests and Water in the Light of Scientific Investigation," by Raphael Zon, Forest Service, U. S. Dept. of Agriculture, 1927.

[76] "Untersuchungen über den Einfluss des Waldes auf den Stand der Gewässer," by Arnold Engler, Schweizerischen Zentralstadt für das forstliche Versuchswesen Mitteilungen, Vol. 12, 1919, Zürich, Switzerland; also "Partnership of Wood and Water," by Hans Burger, *American Forests*, April, 1932, p. 147.

With particular reference to conditions in Southern California, Mr. Cecil states,

"This vast sum [well over $1 000 000] is expended [annually] not for the purpose of protecting a commercial timber supply or, for the most part, even a growth of tree species. The cover is, in the main, chaparral * * * [maintained] on the assumption that: (1) It is a conserver of water; (2) it controls erosion; (3) it retards flood run-off; and (4) recreational value would be impaired by its removal."

That the chaparral cover "conserves water" has not been demonstrated. The question at issue, therefore, is whether chaparral or some other cover best fulfills the other intended purposes.

The balance between soil, topography, run-off, rainfall, and vegetation in natural undisturbed water-shed units does not necessarily represent optimum conditions of water supply. It is fairly well demonstrated that a minimum of vegetative cover will be reflected in a maximum water yield. Mr. Zon[76] states this same principle: "The more highly developed the vegetal cover the faster the moisture is extracted from the soil and given off into the air. In this respect, forest is the greatest desiccator of the soil." If chaparral represents a minimum vegetal cover that will diminish or retard erosion and increase the absorptive capacity of the soil, and if the cost of protecting it from fire is commensurate with the benefits received, then the community expenditure of more than $1 000 000 per year for chaparral protection is justified.

Mr. Tracy I. Storey,[77] presents evidence indicating that when burning of certain chaparral areas was practiced in California, herbaceous vegetation was plentiful, "but since burning has been prohibited herbaceous vegetation and grasses are screened out by the growth of chaparral." Apparently, some thought should be given to the advisability of continuing a policy of retaining, through rigid control at vast annual expense, an inflammable cover that is useless for man or beast when it appears that, in parts of California, at least, restricted burning of chaparral areas will permit the growth of herbaceous grasses that would have economic value for grazing and also a water-shed "protective value." The same thought is also expressed by Mr. Willoughby.

On account of the necessity for economy in cost of publication, the original paper was greatly condensed. Necessarily, in so doing, as Mr. Cecil states, "several factors * * * that are important * * * have been overlooked entirely, and others have not been given proper value in arriving at a conclusion."

With the possible exception of erosion it is believed that in the main any omissions from the original paper have been covered in the various discussions. Although the original paper dealt principally with the effects of forests on stream flow, it was realized that the subject of erosion is intimately connected with the problem under consideration. The writers stated, that: "In the Southern California area complete denudation increased erosion as a direct result of the increased surface run-off" and "deposition of eroded material and ash carried by the streams during the first year after the fire was materially injurious to agricultural lands and transportation rights of way below the canyon." Unquestionably, the eroded material was a source of expense and inconvenience. Floods and attendant erosion, however, have been occurring in this region for centuries prior to the settlement of Los Angeles County.

---

[77] "Factors Influencing Wild Life in California, Past and Present," *Ecology*, October, 1932, p. 323.

E. C. Eaton, M. Am. Soc. C. E., to whom Mr. Cecil refers, states,[78]

> "Take Los Angeles County as an example; it consists of a broad sloping valley area with a background of high mountains roughly equal to the valley area, from which ages of erosion have built deltas to known depths of more than 1 000 ft. * * * The tremendous area and great depth of the gravel cones are in reality of the greatest benefit to this southern County. * * * These underground reservoirs are responsible for the entire early development of the County and supply two-thirds of the water used in the County to-day."

Messrs. Cecil, Gilman, and Lowdermilk infer that the increased run-off made available through diminution of forest cover is non-usable and wholly destructive. Their inference may not be correct.

It is a well-known fact that a large part of the water supply in Southern California is pumped from underground basins and that as a means of increasing the ground-water storage spreading grounds have been established at various points, generally along the mountain fronts. Experience has shown that water which carries suspended matter is not readily absorbed on these spreading grounds. If the present spreading grounds were the sole entry of water into the natural underground reservoirs, there would be a sounder basis for the objections raised against the contentions in the paper. In discussing the question, however, several important facts have been apparently overlooked. In the first place, spreading operations are ordinarily conducted at a time when the entire stream flow would naturally be absorbed by stream channels and none wasted in the ocean. The Santa Ana spreading ground is practically the only exception, and here spreading operations are carried on only when there would be wastage of water to the ocean. It is common practice to let muddy water pass diversion gates in order to safeguard favorable conditions of spreading grounds to receive clear water.

TABLE 25.—CHANNEL ABSORPTION IN SANTA ANA RIVER*

† Including run-off of Santiago Creek, near Villa Park, Calif.

This same muddy water, however, which seems to be waste from the viewpoint of the observer at the spreading grounds, forms one of the largest contributions to the ground-water from the rainfall in the mountain area. Tables 25 and 26 show that muddy water can be and is passed into ground-water.

---

[78] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 198.

According to Harold Conkling,[79] M. Am. Soc. C. E., during the month of April, 1926, while 15 500 acre-ft was absorbed in the San Gabriel River channel above El Monte, only 604 acre-ft was spread at the mouth of the canyon. On the Santa Ana River more than 4 500 acre-ft of water too muddy to spread was absorbed on February 9 and 10, 1932, in a stretch of river channel not longer than 6 miles between Prado and Santa Ana, and constituted a source of ground-water supply for the Santa Ana section. This is twice as much water as the Santa Ana Water Conservation Association spread during the entire season.

* "San Gabriel Investigation", *Bulletin 7*, Div. of Water Rights, California Dept. of Public Works, 1929.

Apparently, the natural river channels below the spreading grounds play an important part in water conservation, and floods exercise an important function in maintaining these channels in condition to absorb water. Mr. Conkling states that,[80]

> "The rate of percolation, particularly where the stream bed contains gravel and boulders, is much less before a major flood than after such a flood. This is due to what is generally called the disruptive effect of a flood. As the water is receding, in some years at least, a thin coat of weakly cemented material is deposited in the stream channel. * * * When a flood occurs big enough to disturb the stream bed this crust is washed away and percolation rates become a maximum."

The writers do not recommend as Mr. Bates implies, the reversal of "great constructive forces of Nature." They do, however, suggest that a change should be made in the concepts to be implied by the term "water-shed protection." Heretofore, undue and in the main erroneous emphasis has been laid on "increasing the water supply," "securing favorable conditions of flow," and "promoting and protecting navigation." These concepts have been widely controverted, and it is evident that no general agreement can be reached in regard to them. The writers would emphasize their belief that water-shed protection as a means of "retarding erosion," "conserving soil," and "lessening torrential run-off," may be obtained by a cover of shrubs or grass, which may use relatively little water, as well as by trees, which may consume large quantities of water. This belief seems logical and scientifically sound and offers a platform on which engineers, foresters, and conservationists might fully agree. So considered, water-shed protection may be reasonably undertaken where physically and economically practicable and where it is clear that commensurate benefits will be obtained.

[79] "San Gabriel Investigation," by Harold Conkling, *Bulletin 5*, Div. of Water Rights, California Dept. of Public Works, 1927.

[80] *Loc cit., Bulletin 7*, 1929, p. 56.

The Editors of the *Journal of Forestry* stated,[81]

> "The Hoyt-Troxell report has had wide circulation; from several parts of the world we learn that it has misled engineers as to the value of water-shed cover for the region in which the study was conducted."

The paper has apparently aroused interest, but it is sincerely hoped that it has not misled any one as to the value of water-shed protection. The objects of the paper will have been partly attained if those concerned with problems of water-shed protection realize that the proper solution is not solely one of silvics in relation to the head-water area, but involves a knowledge of geology, hydrology, hydraulics, and water utilization, and their relation to the entire area.

The discussion of the paper has been sufficiently complete to warrant certain definite suggestions for effective methods of increasing the water yield in the Southern California area and possibly other areas without resulting detriment. Such discussion, however, seems to be beyond the scope of the paper. Because of the limits in scope the writers have also refrained from discussing many related questions which were not covered in the original paper, but which were raised by Messrs. Sopp, Cecil, Gilman, and others. The prolonged discussion of them would cloud the principal purpose of the paper, which was to present to the Engineering Profession and to scientists in general, cumulative evidence of reliable investigations under natural conditions as to effects of trees and brush. As Mr. Randell states this evidence is to the effect that "forests and brush do not increase, but instead considerably lessen, both total water supply and low-season stream flow."

TESTS OF RIVETED AND WELDED STEEL COLUMNS

By Willis A. Slater,[1] and M. O. Fuller,[2]
Members, Am. Soc. C. E.

With Discussion by Messrs. Raymond J. Roark, Lyndon F. Kirkley, R. A. Caughey, E. G. Walker, M. Holt and R. G. Sturm, and M. O. Fuller

Synopsis

The tests reported in this paper were undertaken to secure a comparison of the behavior and strength of built-up steel columns fabricated by riveting, with similar columns fabricated by welding. The program included nine columns, of which two were riveted and seven were welded. In four of the welded columns, the welding was continuous throughout the length. In the other three welded columns, intermittent (or stitch) welding was used. The lengths (to the nearest inch) were 19 ft. 8 in. for three of the columns, 16 ft. 6 in. for two, 15 ft. 5 in. for three, and 5 ft. 6 in. for one.

The columns were built up by riveting or welding cover-plates to the **H**-section or the **I**-section which formed the core. The total cross-sectional area ranged from 14.26 to 24.3 sq. in. in different columns. All were tested as flat-ended columns. Observations included measurement of strains, slip of plates, deflection of column due to the applied load, and strains caused by plastic flow of the heated metal and by the stress set up when the heated metal cooled. In general, the strains were measured in various positions in cross-sections at the top, middle, and bottom of the column. These observations gave the basis for determining the bending moment distribution between the ends and the center of the column. Tension test coupons from various positions in the cross-section were used to determine the variation of yield-point stress throughout the section.

Note.—Published in September, 1932, *Proceedings*.

[1] Research Prof., Eng. Materials, and Director, Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa. Professor Slater died on October 5, 1931.

[2] Associate Prof., Civ. Eng., Lehigh Univ., Fritz Eng. Laboratory, Bethlehem, Pa.

A special feature was the testing of the column having an excessive initial curvature for comparison of strength, bending moment, and deflection, with those of a similar straight column.

1.—THE COLUMNS

The program herein reported, included the testing, during 1928 and 1929, of nine built-up steel columns, each consisting of a core, formed by an **I**-beam or an **H**-section, and a cover-plate attached to each flange of the core. Fig. 1 shows the details of the columns, including the methods of attaching the cover-plates to the flanges. In Columns Nos. 1, 1*BB*, 3, and 4, reinforcing plates were welded to the core section with a continuous bead. In Columns Nos. 2 and 5, plates were riveted to the core section. In Columns Nos. 6, 7, and 8, plates were welded to the core section with an intermittent bead.

FIG. 1.—DETAILS OF COLUMNS TESTED.

Column No. 1 was so much out of alignment that a new column, No. 1*BB*, was furnished to take its place. However, Column No. 1 was tested in order to study the effect of its lack of alignment on its behavior under load. Previous to testing each column, its departure from a straight line in the direction of each of two planes was measured, one plane perpendicular to, and the other parallel to, the plane of the web. These departures are shown in Fig. 2. Except for differences in method of fabrication, Columns Nos. 4, 5, and 7, and Columns Nos. 3 and 6 were designed to be counterparts of columns of Types 6 and 6*A*, respectively, tested at the Bureau of Standards for the Special Committee of the American Society of Civil Engineers on Steel Columns and Struts.[3] The Special Committee provided three lengths in each type of column, and the columns here reported were originally of the intermediate length. However, in this series of tests, in order to provide material for coupons, 1 ft. was cut from the end of each column, making them 1 ft. shorter than the corresponding columns tested for the Special Committee.

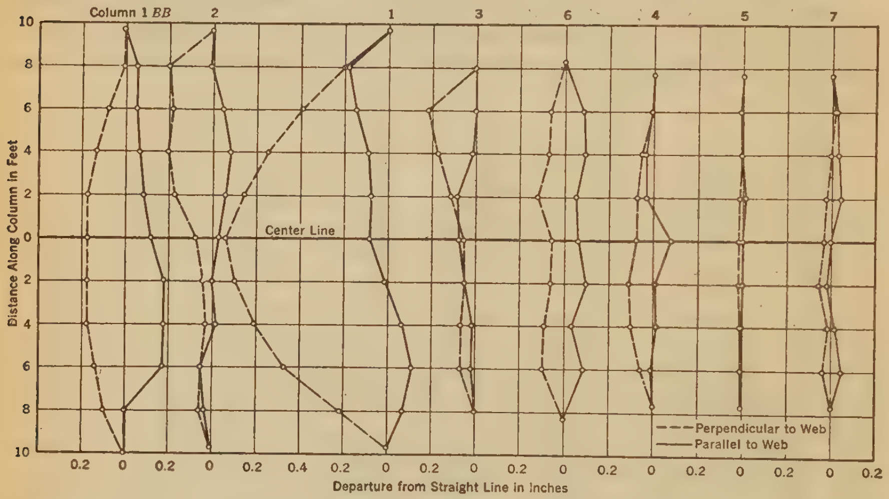

FIG. 2.—INITIAL ALIGNMENT OF COLUMNS.

The columns were tested with "flat ends" as nearly as this condition could be approached. The top and bottom of each column had been milled, but the milling did not give surfaces as nearly plane as might be desired. It is believed that lack of planeness of the ends affected somewhat, the location of the load line in the columns as the loads were applied. Details of methods of testing are given in the Appendix. The data of the test specimens are given in Table 1.

Nomenclature.—The term, "strain line," introduced in this paper, is used to designate the markings that appeared in the white cement coat (which had been applied to all the columns prior to testing) when the mill scale flaked off due apparently to the condition of stress in the steel. The expression, "unit deformation," and the word, "strain," are used to mean the change of length per unit of length, and the word, "stress," to mean the intensity of the internal force per unit of sectional area.[4] The expression, "unit deformation," is applied to a change of length due to any cause such as stress, or expansion due to heat, while the word, "strain," should be applied only to a change of length caused by stress. However, it is not always possible to determine what is the principal cause of a change of length and there may be some confusion in the use of the two terms. In the following notes the term "inside" or "interior" face of a cover-plate or of a flange, refers to the face toward the center of the column. Similarly, "outside" or "exterior" face refers to the face away from the center of the column.

2.—PHENOMENA OF TESTS

The visual phenomena of the tests consisted principally of the formation of the "strain lines" in the whitewash caused by the buckling or flaking of the mill scale. Their occurrence is described in considerable detail for Column No. 4 which may be considered as representative. The significance of the strain lines in general is discussed in Section 4.

Strain lines first appeared in Column No. 4 (welded) at an applied load of 266 kips (approximately 19 kips per sq. in.). They appeared along lines extending horizontally from the edges toward the centers of the cover-plates for a distance of about 2 in. None was appreciably longer than 2 in. Strain lines were first observed near the top after which they extended rapidly over the entire length of the column. They occurred in pairs, one appearing on the outside face of the cover-plate for each one on the inside face. The vertical distances between the strain lines on the outside and inside faces were seldom more than $\frac{1}{8}$ in. With the machine stopped at a load of 266 kips, the number of strain lines continued to increase, but did not extend beyond 2 in. from the edge of the plate, nor did any appear on the I-section. A few forked slightly near their ends.

---

[4] *Proceedings*, Am. Soc. for Testing Materials, Vol. 25 (1925), Pt. I, p. 897.

Under an applied load of 308 kips (approximately 22 kips per sq. in.) strain lines appeared in the I-section, extending from the fillets outward toward the edges of the flanges (Fig. 3). These strain lines at first were about $\frac{3}{8}$ in. long. As the load increased they extended slightly, but never reached a length greater than $1\frac{1}{4}$ in., and did not extend into the web. Some of them were inclined, but generally they were horizontal. At the same load (308 kips) strain lines were found on the outside of the cover-plates crossing the plane of the web at the top within about 3 in. of the end of the column. As the loading continued, these strain lines extended and became more pronounced. Those that had developed earlier in the test showed more forking at the ends.

The distribution of strain lines after the completion of the test is well shown in Figs. 3 and 5. The flanking of the whitewash merely accentuated the phenomenon of the separation of the mill scale from the steel. At places, patches of mill scale of considerable size separated from the metal. In Fig. 3 the shapes of the strain lines are shown for the web and the inner faces of the flange. The uniformity with which the strain lines in the web of the columns extended, about 2.5 in. on either side of the vertical center line of the column, is notable, as well as the regularity with which the strain lines in the flanges began at the fillet and terminated at a vertical line about 1.5 in. from the fillet.

The location of strain lines on the exterior face of the cover-plates, corresponds closely with that of the strain lines on the interior face of the cover-plate and the flange of the I-beam. Most of the strain lines were horizontal at the time of reaching the maximum load. After reaching the maximum load the testing machine was kept running until the load had decreased to about 500 kips. The photographs were taken after the completion of the test, and figures formed by the flaking show many more diagonal lines and much more forking than were present at the maximum load. The vertical line that appears in Fig. 5 at about the position of the web of the column is not due to strain in the plate, but to accidental abrasion of the whitewash. There were no strain lines at the junction of the plate with the I-section. At the higher loads the column deflected markedly in a direction at right angles with the web. No other marked phenomenon of failure appeared.

With most of the columns, the cause of failure appeared to be a deflection over the entire length in a plane at right angles with the plane of the web. In Columns Nos. 5 and 7, however, local buckling of the cover-plates between points of attachment took place at the maximum load, and this apparently was the immediate cause of failure. Both these columns had 11 by $\frac{5}{16}$-in. cover-plates.

In Column No. 5 the buckling occurred on only one side, at about mid-height where the rivets were 5 in. apart in the vertical direction. It had been noticed at the beginning of the test, before any load was applied, that the plate which buckled was slightly bent at the bottom bearing, but there was nothing to indicate that this slight crippling had affected the behavior of the column. The average stress on the entire section was approximately 35.8 kips per sq. in. at the time that the buckling occurred.

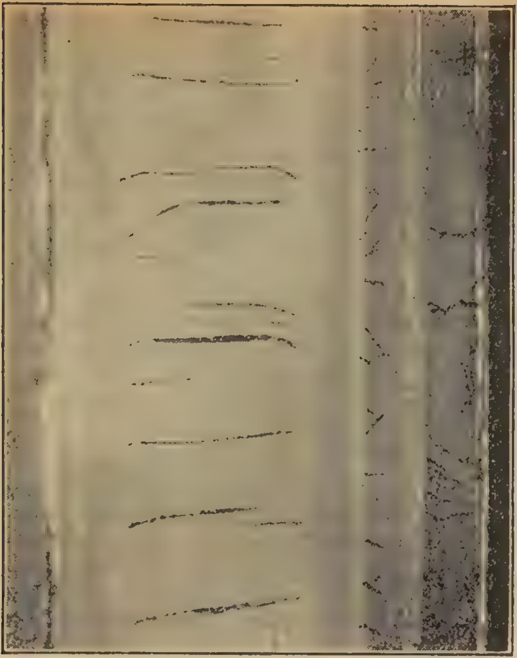

Fig. 3.—Strain Lines on Web of Column No. 4.

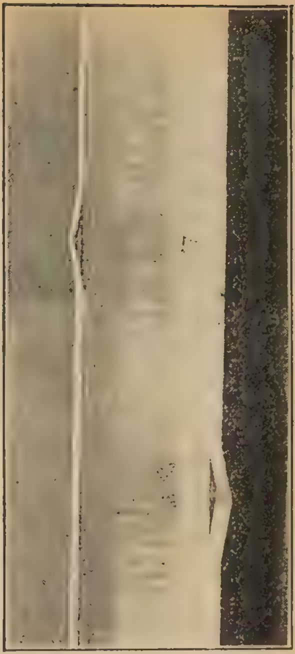

Fig. 4.—Column No. 7 After Test Showing Strain Lines and Buckling of Cover-Plates.

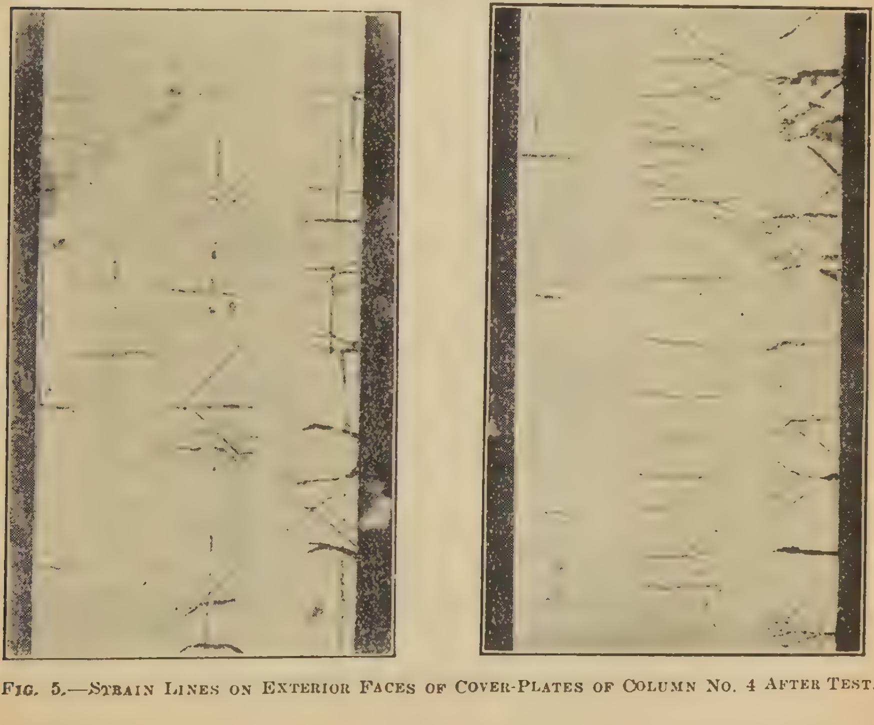

Fig. 5.—Strain Lines on Exterior Faces of Cover-Plates of Column No. 4 After Test.

In Column No. 7 the buckling occurred in both cover-plates, one at 10 in. and the other at 31 in. below mid-height, as shown in Fig. 4. In this column the distance from center to center between the 2-in. stitch-welds, was 10 in. No defects in the welds at the points of buckling were observed. Buckling of the plates occurred in both the riveted and the stitch-welded columns with $\frac{5}{16}$-in. cover-plates, but did not occur in either the riveted or the stitch-welded column with $\frac{5}{8}$-in. cover-plates. The ratios of the rivet or weld spacing to the thickness of plates are given in Table 2.

tive to a point on the **I**-section or **H**-section. These gauge lines were placed only on Section *B* at the top of Column No. 4, and on both Sections *B* and *D* for Columns Nos. 1*BB*, 2, 3, 5, 6, and 7, since it was believed that if slipping occurred at all, it would be near one end of the column. Gauge Lines *B*11 and *B*11*b* are shown in Fig. 6(*e*). Gauge Lines *B*5, *B*5*b*, *B*17, *B*17*b*, *B*23, and *B*23*b*, are similarly arranged. Fig. 7 presents some representative curves showing the movement in various gauge lines. They have been plotted in pairs, both gauge lines of each pair being referred to the same origin. The dotted lines are the graphs for Gauge Lines 5, 11, 17, and 23, and the solid lines are for Gauge Lines 5*b*, 11*b*, 17*b*, and 23*b*. The numbers designating the gauge lines are shown near the origin of the respective graphs. The capital letters, *B* or *D*, indicate whether the measurement was at Section *B* or Section *D*, and the Arabic numerals indicate the position of the gauge line in the section. (See Fig. 6.) Similar sets of curves were drawn for the other columns.

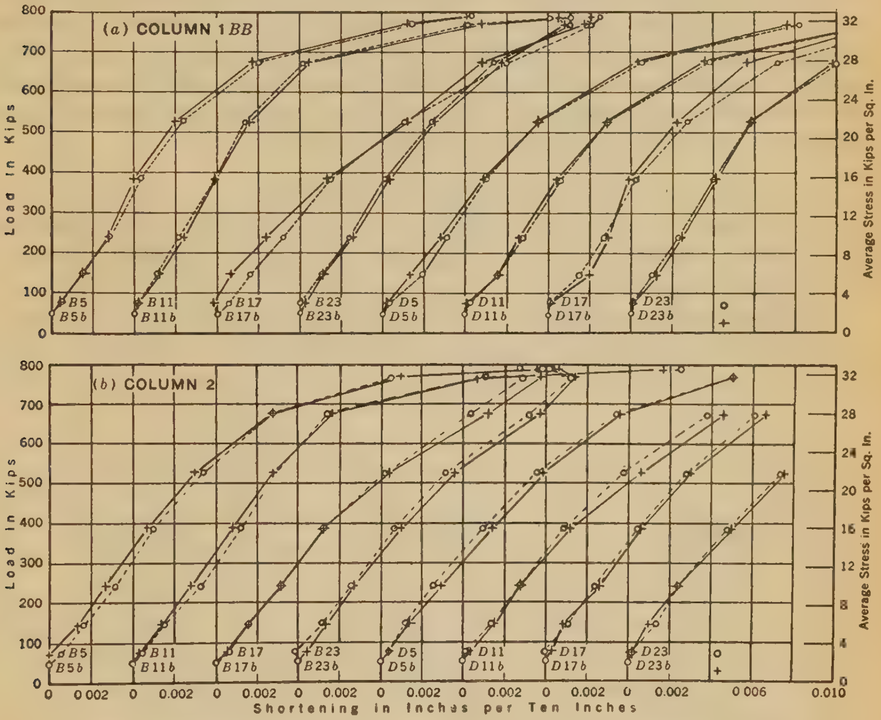

FIG. 7.—STRESS-STRAIN CURVES FOR DETERMINATION OF SLIP OF PLATES.

If there were no slipping of the plates, and no error of observation, the dotted lines and the solid lines should coincide. Any divergence indicates either error of observation or slipping of the plates, or both. Since there is certain to be some error of observation, some divergence of the lines is inevitable. If an error occurs in the zero reading, it will cause the dotted and the solid graphs to remain at a fixed horizontal distance apart; if it occurs in readings for loads above that for the zero reading, it will cause an erratic divergence and convergence of the graphs. Slipping of the plate with reference to the structural shape should be expected to increase with increased load, and, therefore, should cause a progressive divergence of the graphs.

The curves, including those in Fig. 7, show many erratic divergences and convergences of the lines, most of which are slight, indicating slight errors in the measurements. There are a few slight divergences which are progressive over a part of the test, such as that for Gauge Lines *D*17 and *D*17*b*, for Column No. 1*BB*, and that for Gauge Lines *D*11 and *D*11*b*, for Column No. 2 (Fig. 7). These divergences, however, represent at most a slip of approximately 0.001 in., and it cannot be stated positively that it represents a slip at all. On the whole, the practical coincidence of the dotted and the solid graphs in these diagrams indicate that there was little if any slipping of the plates in either the welded or the riveted columns.

4.—Strains and Strain Lines

Fig. 6 shows the positions of the gauge lines. While the cross-sections of the different columns varied, the same plan of gauge numbering was used throughout the series.

Bending strains developed quite early in the test, although the bearings were adjusted in such a way that, at an applied load of approximately 60 kips, the observed strains at the four corners of the column were equal. It was assumed that the over-all shortening, which was used in making the adjustments of the bearing (see Appendix, Article 2), would detect bending strains in the columns due to eccentricity of the bearing. However, an examination of Column No. 4 (see Fig. 8), indicated bending moments at the middle and

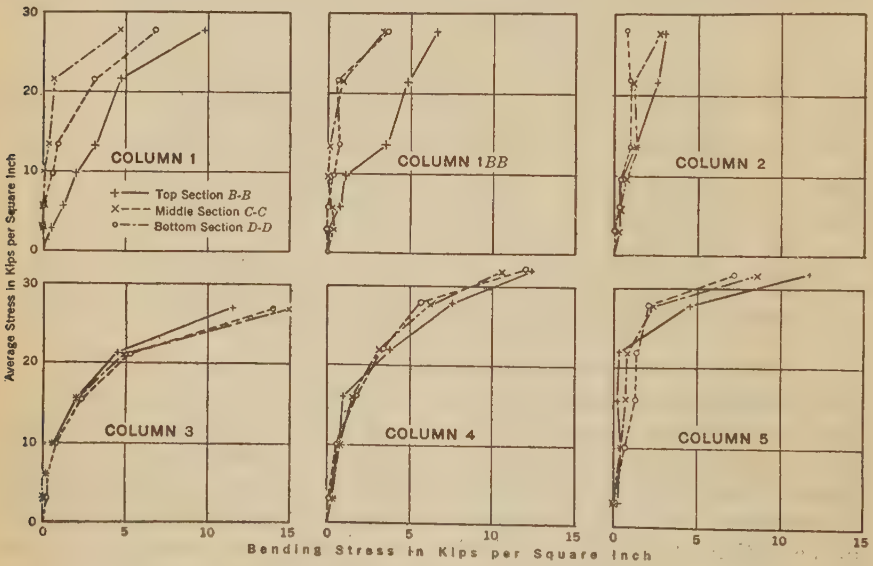

Fig. 8.—Bending Stresses in Columns.

at the ends nearly equal in value and opposite in sign. This reversal of moment tended to equalize the over-all shortening measured on the four corners of the column, and, therefore, reduced the effectiveness of these measurements as an adjusting agent. It is evident that if the over-all shortening at the four corners of the column were equal in spite of large bending moments in the column, the measurement of this shortening would be of no use in detecting eccentricity of load.

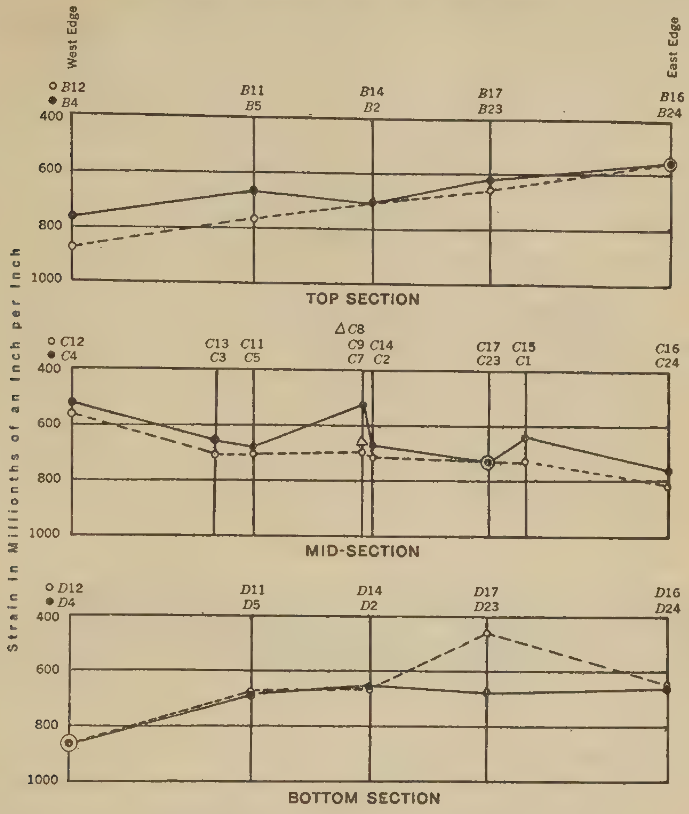

FIG. 9.—DISTRIBUTION OF STRAINS AT SECTIONS OF COLUMN NO. 4 FOR A LOAD OF 308 KIPS, OR A STRESS OF 216 KIPS PER SQUARE INCH.

The presence of bending strains is indicated by the slope of the graphs in Fig. 9, which shows the total measured strains for the cross-sections at *BB*, *CC*, and *DD* of Column No. 4. Fig. 10 shows a pronounced change of slope of the average stress-strain curve at the stress of 21.6 kips per sq. in. Fig. 9 is more or less typical of the strain distribution across the sections of the columns for loads near the critical.

Up to a certain load for each column, the average strain at mid-section was approximately the same as the average for the full length of the column. Above this load the average strain at the center was greater than the average for the full length of the column. This is shown by the divergence of the broken from the solid lines, for the higher loads in Fig. 10.

Figs. 3, 4, 5, 11, 12, 13, 14, and 15 are representative views of the strain lines that appeared in columns of various types and designs during the testing. They were all taken after the completion of the individual tests. Evidently, two major influences affected the number, location, and direction of the strain lines in the whitewash, namely, the weight of the section, and the method of fabrication. In the column of the lighter sections, the strain lines were much more general than with the heavier sections. With the 10-in., 25.4-lb. **I**-sections, the strain lines in the web were closely spaced and prominent, but never extended into the fillets, either from the webs or from the flanges. (See Figs. 3 and 4.) With both the heavier cores; that is, the 8-in., 32-lb. **H**-sections (Fig. 14) and the 10-in., 35-lb. **I**-sections, the strain lines were less general, but they extended entirely across the web and out into the flanges.

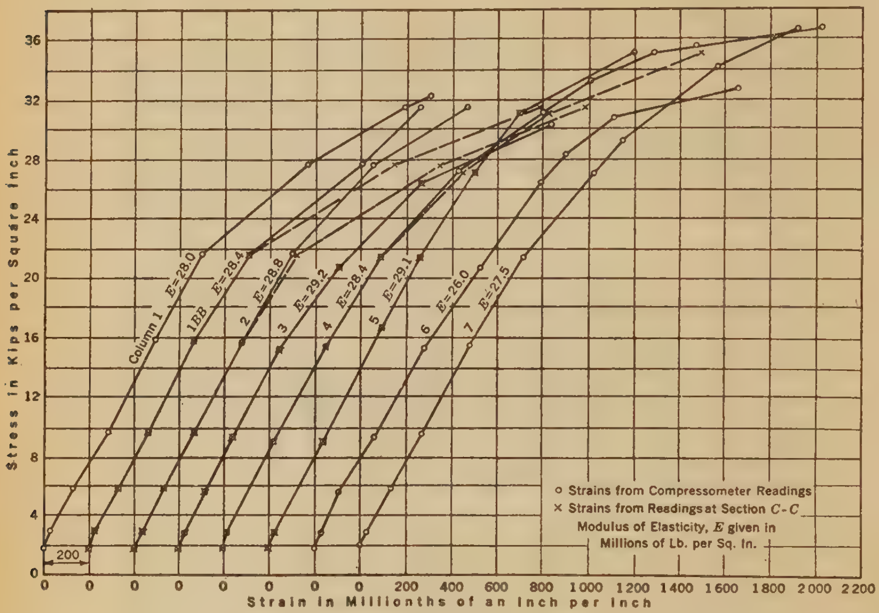

FIG. 10.—AVERAGE STRESS-STRAIN CURVES FOR COLUMNS NOS. 1 TO 7.

No case was found in which a strain line crossed a weld, and only a few in which they crossed the line of the weld on the outer face of the plate; that is, on the face opposite that of the weld (Fig. 15). In the stitch-welded columns (Fig. 4), the same general placement of the strain lines existed as in the columns with the continuous welds, except that in the former the strain lines, generally, were found in groups opposite the welds and seldom in the sections between the intermittent welds. With the riveted columns, the strain lines extended to the edge of the flange and up close to the rivets. (See Figs. 11 and 12.)

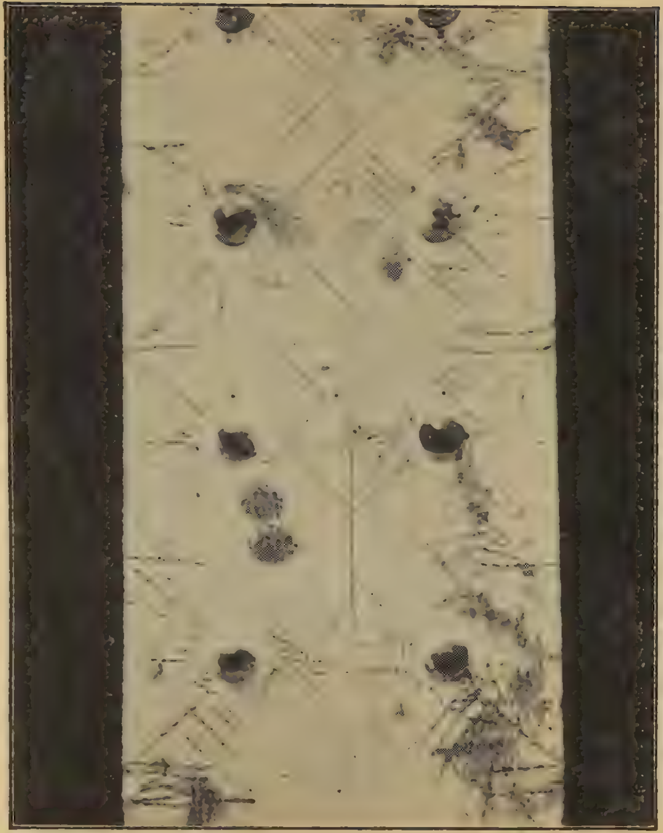

Fig. 11.—Strain Lines on Exterior Face of Cover-Plate of Column No. 2 After Test.

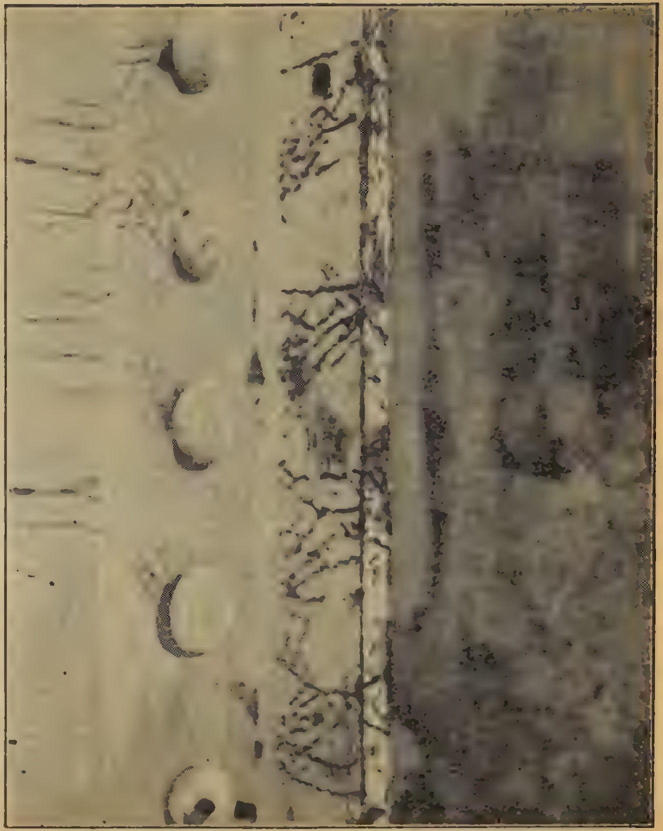

Fig. 12.—Strain Lines on Interior Face of Cover-Plate of Column No. 2 After Test.

In each of the columns the first strain line appeared in one of the cover-plates, generally near the edge, at the stress given in Table 3, Column No. 4. The stress at this time ranged from 21 to 10 kips per sq. in., except for Column No. 6, in which the first strain lines appeared at a stress of 5.8 kips per sq. in. The average stress at which a strain line first appeared in the cover-plates was 15.1 kips per sq. in. The average stress when a strain line first appeared in the web is shown in Table 3 to have ranged from 36 to 22 kips per sq. in. for the various columns.

TABLE 3.—COMPARISON OF COMPUTED STRESSES FOR MAXIMUM LOAD ON COLUMN WITH YIELD POINT STRESSES FROM COUPONS AND WITH STRESSES COMPUTED BY RANKINE'S FORMULA

Column No.	Yield point of coupons, in kips per square inch	STRESS AT FIRST STRAIN LINE, IN KIPS PER SQUARE INCH		Stress at proportional limit of column, in kips per square inch	STRESS AT MAXIMUM LOAD, IN KIPS PER SQUARE INCH		Ratio of stress at maximum load to yield point of coupons	Ratio of stress from Rankine formula to stress at maximum load
		Cover-plate	Web		From test	Computed by Rankine formula		
1	34.9	16.0	22.0	21.8	32.3	27.7	0.925	0.858
1*BB*	35.4	16.0	28.0	21.8	32.3	28.1	0.912	0.870
2	35.9	16.0	32.0	21.8	32.5	28.5	0.905	0.877
3	34.6	21.0	27.0	15.3	30.8	27.8	0.892	0.903
4	38.7	19.0	29.0	36.9	36.9	31.0	0.954	0.840
5	39.2	17.0	36.0	21.4	35.8	31.4	0.913	0.877
6	37.9	5.8	24.0	15.4	33.3	30.5	0.879	0.916
7	39.8	10.0	27.0	15.4	36.7	31.9	0.922	0.869

The stress at which strain lines appear is generally assumed to be approximately the yield point of the steel. For this to have been the case with these columns, requires that there must have been an initial stress at the point where the first strain lines started, averaging about 20 kips per sq. in. There are some reasons for thinking that compressive stresses were set up in the webs of the **I**-beams and **H**-beams by unequal cooling after rolling, but it is not possible from the data of these tests, to estimate their magnitude. Although initial stresses of considerable magnitude due to the heat of rolling and of welding were undoubtedly present, this fact need not be alarming since the strengths of the columns were about what should be expected with the materials, shapes, and lengths used.

5.—EFFECT OF WELDING ON STRAINS AND STRESSES

In a study of the strains due to welding, and their effect on the location of strain lines, Column No. 8 (5 ft. 6 in. long), was fabricated and tested. (See Fig. 13.) Two, 11 by $\frac{5}{16}$-in. cover-plates were stitch-welded to a core that consisted of a 10-in. 35-lb. **I**-beam. The welds at the top and bottom of the column were continuous for 10 in. from the ends. The intermediate welds were each 2 in. long and spaced 8 in. apart, center to center. Previous to the welding of the plates to the **I**-section, numerous 2-in. gauge lines were established and read. These lines were read again after the welding was completed and after the column had cooled down to normal temperature. Load was then

FIG. 13.—STRAIN LINES ON EXTERIOR FACE OF COVER-PLATE OF COLUMN NO. 8 AFTER LOADING TO AVERAGE STRESS OF 27.7 KIPS PER SQ. IN.

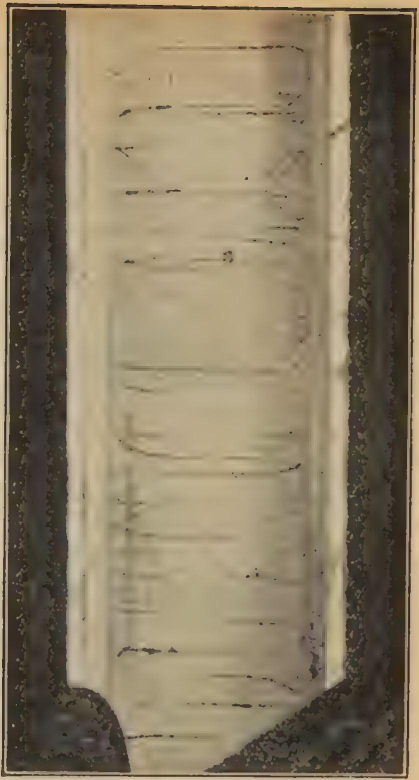

FIG. 14.—STRAIN LINES ON WEB OF COLUMN NO. 1*BB* AFTER TEST.

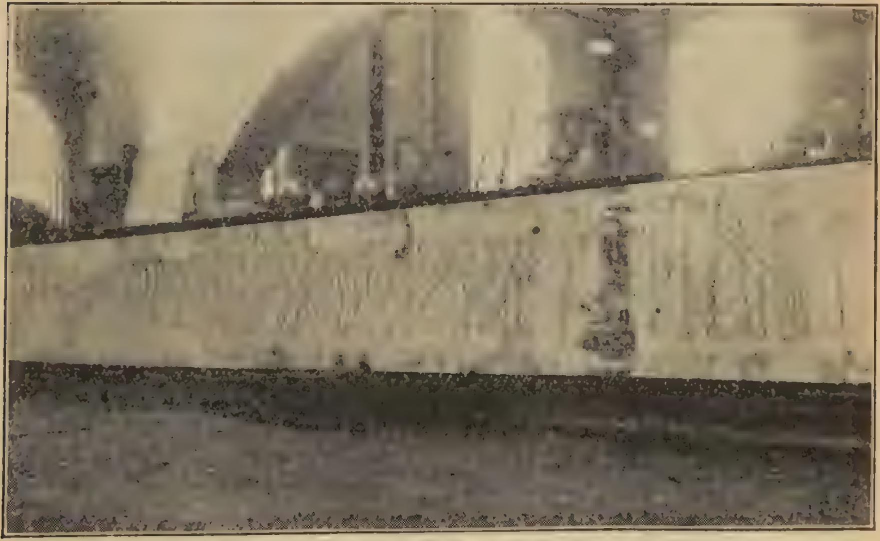

FIG. 15.—STRAIN LINES ON EXTERIOR FACE OF COVER-PLATE OF COLUMN NO. 1 AT MAXIMUM LOAD.

applied up to a maximum of 398 kips, which caused an average stress in the column of 27.7 kips per sq. in. After the strain readings had been obtained this load was removed and another set of readings was taken to measure any permanent set in the column.

Fig 16 shows the location of intermittent welds in relation to the gauge lines used to determine the distribution of the strains in a cross-section at the center of the column and along the edges of the cover-plate for some distance above and below the center. The elevation of the gauge lines is given by letters, and the position on the cross-section, by numbers. For example, *D*-25 was at the mid-height of the column and on the fillet of the I-section.

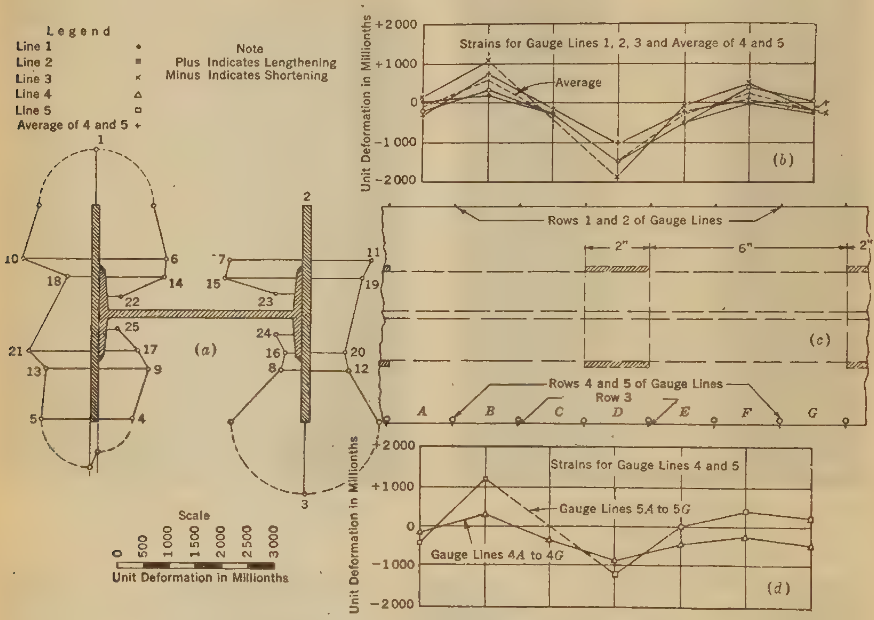

FIG. 16.—STRAINS IN COLUMN NO. 8 DUE TO WELDING.

In Fig. 16 (*a*), the unit deformations in all gauge lines cut by Section *D* at mid-height of the column have been plotted opposite the gauge line in a direction perpendicular to the surface in which the strain occurred. A distance away from the surface represents unit shortening. Evidently, all the gauge lines cut by the section were shortened, although it is unlikely that the stress was compression in all of them, since the total stress on the section was zero. There were no gauge lines on the web, but it does not seem likely that the web was in tension due to bending stresses.

Without some knowledge of how much plastic flow there was, it is impossible to state how many of the resultant deformations shown in Fig. 16 (*a*) represent stress. However, at points in the section so far removed from the weld that plastic flow due to the heat was unlikely, the strains indicate a compressive stress of about 15 kips per sq. in. and it seems likely that at the weld the tensile stress was as great as the yield point of the metal, in spite of the fact that the strain readings showed that it had shortened due to the welding.

Fig. 16 (*b*) shows that at all four corners of the column there was a marked shortening at the section through the welds and a marked elongation at the sections between welds. Sections *B* and *F*, midway between welds, were far enough from the weld so that probably no plastic flow occurred in them. The average tensile strains at the edges of the plates for these two sections were 600 millionths and 250 millionths, respectively. Using the average modulus of elasticity of 29 000 000 lb. per sq. in. the corresponding stresses are 17.4 and 7.25 kips per sq. in. Since the external force on each of these sections is zero, there must have been compressive stresses on other parts of the section to balance the tensile stresses.

The variations of strain along the edges of the plate, as shown in Fig. 16 (*b*), make evident why the strain lines on the welded columns appeared first opposite the welds. Evidently, the heat of welding had set up compressive stresses at these points and tensile stresses at the edges of the cover-plates between them, so that when the load came on the column, the yield point was reached first at points opposite the weld.

Fig. 16 (*d*) shows that the strains on opposite faces of the cover-plate were not equal, but that local bending strains, varying somewhat regularly from weld to weld, took place. These bending strains were probably due to the fact that the heat was applied to only one side of the plate. The difference in strains corresponds to a difference of stress on opposite sides of the plate, amounting at Section *B* to approximately 27, and, at Section *F*, to 19.5 kips per sq. in.

The phenomena pointed out in the foregoing paragraphs make it apparent that there is room for much further study of the effect of welding on stresses in structural members.

Upon application of load to the column, the strains were read and have been plotted in Fig. 17, in which the letters, *B*, *D*, and *F*, refer to positions shown in Fig. 16. The slope of the graphs indicates that the strains increased at approximately the rate to be expected for steel under stress, but beginning in each case with the strain set up by the welding. As a result, the total strains at Gauge Lines *D*1 to *D*21, under the final stress of 27.7 kips per sq. in., were very great. Strain lines formed in the white cement coat at the indicated points of high strain opposite to, and at some distance from, the welds, but none close to the welds. This is consistent with the fact that, as was previously pointed out, tensile stresses must have existed in the immediate vicinity of the welds due to shrinkage on cooling. The absence of strain lines in the welds may have a further explanation since auxiliary tests made on small angles showed no strain lines on the welds, although the load applied caused stresses far beyond the yield point of the steel.

6.—MODULUS OF ELASTICITY

Table 4 gives the moduli of elasticity as determined for certain coupons and for the columns. The moduli of elasticity of the coupons for the core sections and the plates were weighted in proportion to the sectional areas of each, and the weighted average for the entire cross-section of the column was computed. To determine the moduli directly from the tests of the columns the strains in the gauge at mid-height (Section *CC*) were weighted in proportion to the approximate areas of the cross-sections which they represented, and weighted average strains for Section *CC* were computed from these weighted values. These strains were plotted in Fig. 10, and from these stress-strain diagrams the moduli of elasticity, given in the last column of Table 4, were computed.

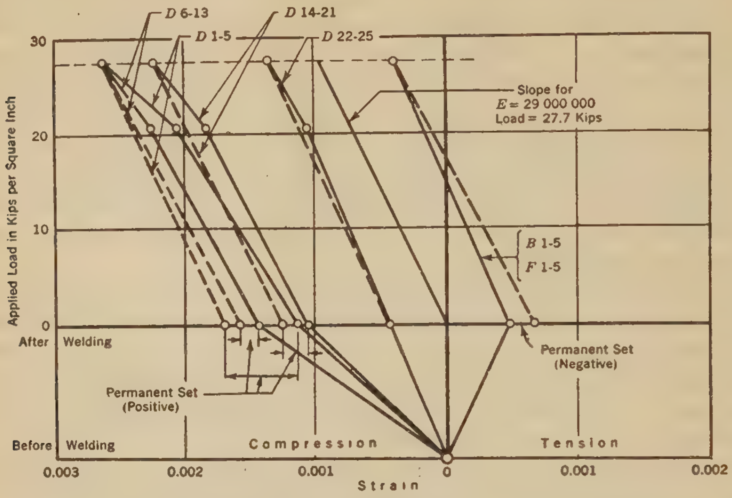

FIG. 17.—LOCAL STRAINS IN COLUMN NO. 8 BASED ON READINGS TAKEN BEFORE FABRICATION.

TABLE 4.—MODULUS OF ELASTICITY OF COLUMNS, IN POUNDS PER SQUARE INCH

Column No.	MODULUS FROM COUPON TESTS			From column tests
	Core section	Plates	Weighted average	
1	29 500 000†	30 000 000†	29 800 000	28 000 000
1*BB*	28 400 000†	30 100 000†	29 500 000	28 400 000
2	31 000 000†	30 400 000†	30 600 000	28 800 000
3	31 300 000†	28 900 000†	29 900 000	29 200 000
4	28 000 000†	27 400 000†	27 700 000	28 400 000
5	27 500 000†	29 100 000*	28 300 000	29 100 000
Average....	29 300 000	29 300 000	29 300 000	28 650 000

* Average for four test coupons. † Average for two test coupons.

Only the first five columns tested, Nos. 1*BB*, 2, 3, 4, and 5, were used for these determinations, since in Columns Nos. 1, 6, 7, and 8, some or all of the gauge lines on Section *CC* were omitted. The extreme range in moduli of elasticity from the coupons tested in tension, was about 10% of the average value. The corresponding range of values from the column tests (compression) was about 3 per cent.

The average modulus from the coupons was 29 300 000 and that from the columns, 28 650 000 lb. per sq. in. The agreement between the two values is reasonably good, and their average is very close to 29 000 000 lb. per sq. in., the value used in the computation of stresses from strains in this paper.

The agreement between the weighted moduli for the columns and the coupons is of interest in view of the fact that tests of two independent structures in recent years reported by Clyde T. Morris,[5] M. Am. Soc. C. E., and A. H. Fuller,[6] M. Am. Soc. C. E., indicated that either (1) the modulus of elasticity of the columns was only about 22 300 000 lb. per sq. in.; (2) the load was about 27% greater than that computed; or (3) errors due to temperature deformations entered the data. Both tests appear to have been conducted so carefully, and the results were so consistent for a large number of columns, as to make it unlikely that appreciable error due to temperature changes or inaccuracy in determining loads was involved.

It was largely in an effort to find out whether uneven distribution of stress over the cross-section could explain the discrepancy in the tests by Professors Morris and Fuller that the gauge lines shown in Fig. 6 were distributed so completely over the cross-section of the column. However, the results of these tests offer no explanation of the unexpected phenomena observed by Professors Morris and Fuller.

7.—Deflections

The initial alignments of the columns as given by measurements on the cover-plates, are shown in Fig. 2. The load-deflection curves are given in Fig. 18, and the deflections at maximum load in Table 5. In both cases the deflection given occurred in the plane of least resistance.

TABLE 5.—Results of Column Tests

* Deflection measured perpendicular to web.

The following discussion of deflections applies to Column No. 4 which was the first column tested. The behavior indicated here may be taken as more or less typical of all except Column No. 1 which is discussed in Section 8 and except Column No. 8 for which no deflections were measured. Column No. 4 was not entirely straight at the beginning of the test. (See Fig. 2.) Each cover-plate had a camber of 0.08 in. at the center in the plane of the plate, but the camber was in opposite directions for the two plates, so that for deflections of the column as a whole, the effect should be nearly the same as if the column had been straight. The camber in opposite directions might tend to introduce a twisting, but if any twist was present it was not large enough to be observed visually.

[6] "Measurement of Stresses in Four Steel Columns of the Equitable Building," *Bulletin No. 72*, Eng. Experiment Station, Iowa State Coll.

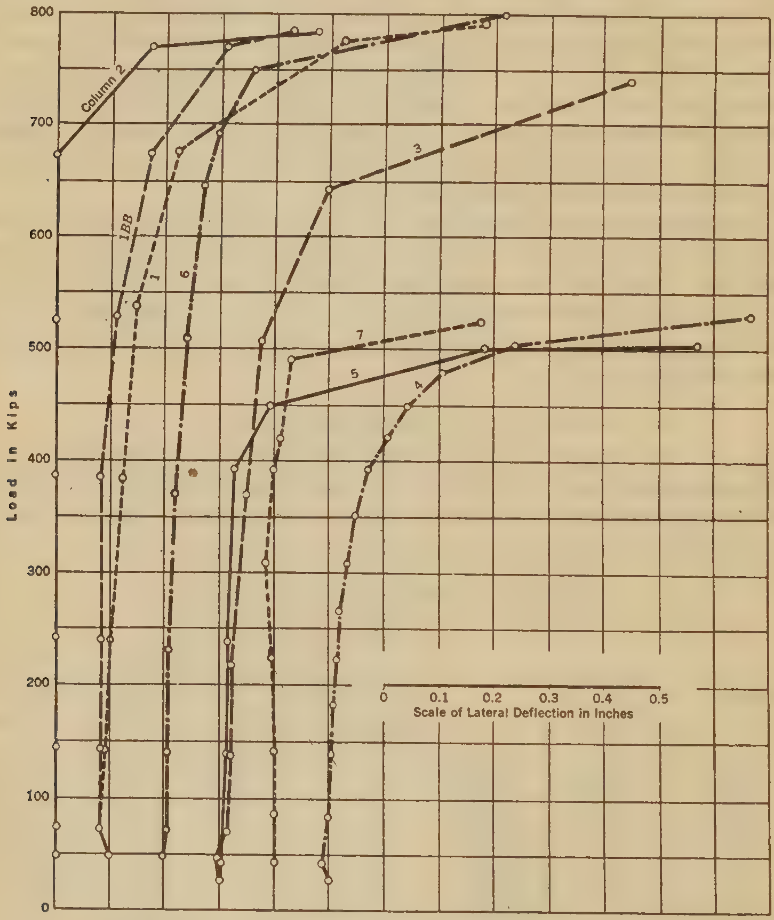

FIG. 18.—CENTER DEFLECTION PERPENDICULAR TO WEB.

Some deflection in the plane of least resistance was apparent almost from the beginning of the test (Fig. 18). At a load of 266 kips, this deflection was 0.02 in. and from that point the deflection increased rapidly, becoming 0.77 in. at the maximum load of 527 kips. Deflection in the plane of greatest resistance began at a load of about 266 kips, the load at which the deflection in the plane of least resistance first began to increase rapidly. From that point, it increased steadily to 0.03 in. at a load of 504 kips, at which time a rapid increase began. At the maximum load of 527 kips, this deflection was 0.06 in. Although the test was continued beyond the maximum load, the instruments had been removed and the deflection was not measured. The principal final deflection took place in the plane of least resistance when, with the testing machine still running, the load had fallen off to about 500 kips. That in the plane of greatest resistance was still not apparent to the eye.

Inspection of Fig. 18 shows that, except at the maximum load, the deflections of the riveted Columns Nos. 2 and 5 were smaller than those of the corresponding Columns Nos. 1 and 4, welded with continuous beads. Fig. 2 indicates that the riveted columns were initially straighter than the continuously welded columns. Fig. 18 shows that Columns Nos. 6 and 7, with intermittent beads, deflected less under load than the corresponding Columns Nos. 3 and 4, with continuous beads. Columns Nos. 6 and 7 were initially slightly straighter than Columns Nos. 3 and 4. Still another comparison may be made. Columns Nos. 4, 5, and 7, were alike except that Column No. 5 was riveted, Column No. 7 was welded with an intermittent bead, and Column No. 4, with a continuous bead. The magnitudes of the initial departures from a straight line increased in the order given—namely, Columns Nos. 5, 7, and 4—whereas the deflection under load was least for Column No. 7 (intermittent weld), next larger for Column No. 5 (riveted), and largest for Column No. 4 (continuous weld).

In all comparable cases the deflections were largest for the columns welded with the continuous bead. Only one comparison between a riveted column and a column with intermittent bead could be made, and the deflection was less for the intermittently welded, than for the riveted, column. The two comparisons available showed the deflection for the intermittently welded, to be less than that for the continuously welded, column.

The columns fabricated by riveting were straighter than those fabricated by either continuous or intermittent welding. The magnitude of deflection under load corresponded to the magnitude of the initial departures from straightness, except that the riveted column (No. 5) gave greater deflection under load than the less straight column (No. 7), which was welded with intermittent beads.

In general, the differences in deflection were small and only one column of a kind was tested. Therefore, it should not be concluded that these statements represent in general the relation between deflections of riveted and welded columns.

8.—Bending Stresses

The averages of the measured strains for Gauge Lines 4 and 12, and for Gauge Lines 16 and 24, were computed separately. The former represents the strain on the west, and the latter, the strain on the east, edges of the cover-plates. One-half the sum of these average strains represents the average strain over the entire cross-section and one-half their difference represents the bending strain in the "extreme fiber," provided that (1) the strains were measured correctly; and (2) a plane section before bending remained plane after bending. These strains, multiplied by 29 000 000 lb. per sq. in. (the average modulus of elasticity for all columns), give the average stress, $\frac{P}{A}$, and the bending stress, respectively.

A comparison of the average stress thus computed, with the total loads divided by the area of the columns—that is, $\frac{P}{A}$—is given in Fig. 19. The two curves for average stress agree closely for the lower loads. This agreement should be expected up to a point at which the maximum stress is near the yield point of the material, but a marked divergence takes place at a value of $\frac{P}{A} = 21$ kips per sq. in. for Column No. 1*BB*, and at a value of 16 kips per sq. in. for Column No. 2 (total loads, 510 and 336 kips, respectively), whereas the yield point of the coupons occurred at a stress of about 35 kips per sq. in. for each of these columns (Table 6). It is possible that, due to the presence of initial stresses, the limit of proportionality between stress and strain had been reached at certain places, under comparatively low average stresses.

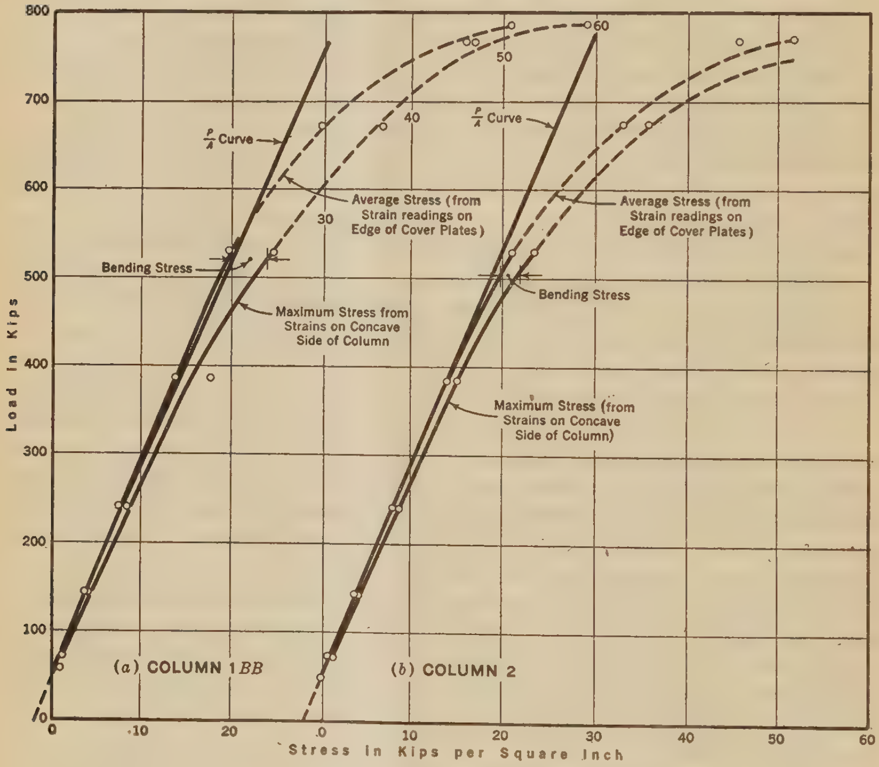

FIG. 19.—LOAD STRESS CURVES.

* Average of six test coupons. † Average of eight test coupons. ‡ Average of twelve test coupons.

Fig. 8 is a summary of the bending stresses for Columns Nos. 1 to 5, inclusive. The relation between bending stresses at the top, middle, and bottom for Column No. 1 is shown in some detail in Fig. 20. In all cases

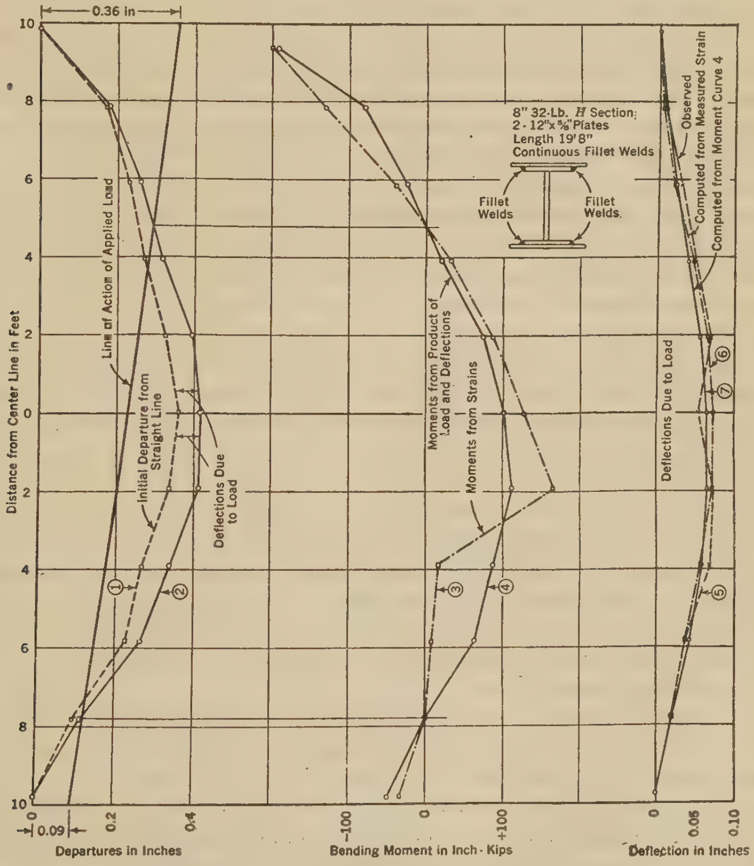

FIG. 20.—DEFLECTIONS AND BENDING MOMENTS FOR A LOAD OF 528 KIPS, COLUMN NO. 1.

the bending stresses at the top and bottom, Sections *BB* and *DD*, are opposite in sign from those on the same side of the column at the mid-section, *CC*, although all were plotted in the same direction for convenience. In Columns Nos. 3, 4, and 5, the bending stresses at the top, middle, and bottom were about equal, as would be the case if the columns were fixed at the top and bottom. In Columns Nos. 1, 1*BB*, and 2, the bending stresses were greater at the top than at the middle, indicating some initial eccentricity of loading in the columns. There is nothing in Fig. 8 to indicate any marked advantage of either riveted or welded columns over the other, as far as freedom from bending moments is concerned.

Strangely enough the bending stress seems to have had little effect on the maximum loads carried. This is shown by the fact that the ratio of the stress at maximum load, to the yield-point stress of the material (given in Table 3), was nearly constant for all columns.

9.—Bending Moments and Deflections in Column No. 1

In the test on Column No. 1, longitudinal strains were measured on the four corners; that is, on the edges of the cover-plates, at sections approximately 2 ft. apart, throughout the length of the column. At the same sections deflections were measured parallel to, and perpendicular to, the web of the column. The deflections due to a load of 528 kips were added to the initial departures from a straight line and the resulting total departures (Fig. 20, Curve 2), indicate the total curvature in the same plane under this load.

It was desired to ascertain whether the deflections of this column under load were those that should be expected with a column having as much initial curvature as this one possessed. This question appears to be of the greater significance as Column No. 1 carried a maximum load (785 kips) slightly in excess of that (784 kips) carried by the much straighter column, No. 1*BB*, which otherwise was similar to it.

For the load of 528 kips, the bending moments about a gravity axis which was parallel to the web of the columns were computed from the measured strains for all sections at which strain-gauge measurements were taken. For these computations the usual formula, $M = \frac{SI}{c}$, was used, in which, M is the moment of the internal stresses; S is the bending stress; I is the moment of inertia of the column section about the gravity axis to which the moment is referred; and c is the distance from the gravity axis to the extreme fiber, that is, one-half the width of the plate. The strain used in computing the stress, S, was one-half the average difference of the strains measured on the opposite edges of the cover-plates. A modulus of elasticity of 29 000 000 lb. per sq. in. was used.

The bending moments computed in this manner have been plotted in Curve 3 of Fig. 20. It will be noted that there were two points of zero moment within the length of the column. Since the bending moment is equal to the product of the load times the distance of its line of action from the center of gravity of the section of the column, the line of action of the load must pass through the center of gravity of the sections of zero bending moment. This fact was used to locate the line of action of the load. Projecting the two points of zero moment horizontally from Curve 3, to intersect Curve 2, two points on the line of action were established. A line passed through these points indicates that there was an eccentricity of the load equal to 0.36 in. at the top of the column and to 0.09 in. at the bottom. Multiplying the load by the departures of its line of action from the center line of the deflected column gives the moments at the various sections. These moments have been plotted in Curve 4 for comparison with those found from the strains.

While there are certain marked disagreements, the general agreement between these two moment curves, 3 and 4, is good. From each moment curve (that is, that obtained directly from the strains, and that from the product of the load times the departures), the deflections have been determined by a double integration of the $\frac{M}{EI}$-curve for the column. The measured deflections and the deflections computed by the two methods have been plotted in Curves 5, 6, and 7, for comparison with each other. Since the deflection curve could have been determined directly from the measured strains instead of first using the strains to compute the moments, the deflection curve, 6, has been designated as that computed from the measured strain. In determining the deflections given in Curve 7 the moments computed as loads times departures were used. The agreement between the two methods (which is very good), indicates that there was nothing mysterious in the behavior of the column so far as deflections are concerned. It is not clear, however, why Column No. 1 carried a slightly larger load than Column No. 1*BB,* in spite of the lack of alignment of Column No. 1. The explanation is not to be found in a difference of the yield points of the steel for the two columns, since this was only 0.5 kip per sq. in. The weighted average yield point for Column No. 1 was 34.9 kips per sq. in., and that for Column No. 1*BB* was 35.4 kips per sq. in. In spite of its greater initial straightness, the maximum bending stress at the load of 528 kips was greater in Column No. 1*BB* than in Column No. 1, and this may account for the fact that Column No. 1 carried slightly more load than Column No. 1*BB*. Possibly, the lack of planeness of the ends of the columns had more to do with the development of bending stresses than the lack of initial straightness.

It was unexpected to find an eccentricity of 0.36 in. for the resultant load at the top and an eccentricity so much greater there than at the bottom. As indicated in the Appendix, Article 2, much care was used in centering the columns. However, as shown in Fig. 8, bending strains were found early in the tests. Although the column ends were milled, they were not plane enough to provide uniform contact with the bearing-plate, and this lack of planeness seems to be the most probable cause of the eccentricity.

10.—Proportional Limit and Maximum Load

The stress at which any curve in Fig. 10 departed appreciably from a straight line was taken as the proportional limit for the column represented by the curve. The values thus determined are given in Table 3. The proportional limits for Columns Nos. 3, 6, and 7, are so low as to raise some doubt as to the validity of the values selected, but for Column No. 3 the points determined by the strain gauge and those determined by the compressometer readings for the full length of the column coincide throughout the curve, giving confirmation to the value chosen as the proportional limit. For Columns Nos. 1*BB*, 2, 4, and 5, the points determined by the strain gauge coincide with those from the compressometer up to a high load. For Columns Nos. 1, 6, and 7, strain-gauge readings for plotting the average strains were not taken, therefore, no comparison between proportional limit by the two methods was available.

It has been indicated quite clearly that the presence of initial compressive stresses at any position hastened the appearance of strain lines at that position. The stresses at the proportional limit, as shown in Table 3, were higher than the stresses at the first appearance of strain lines, yet there is a general correspondence between the two sets of values which suggests that the presence of initial stresses affected the limit of proportionality between applied stress and resulting strain.

Table 3 gives a comparison of the strengths computed by the use of the Rankine formula,

$$\frac{P}{A} = \frac{S}{1 + \frac{1}{25\,000}\frac{l^2}{r^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

with the stresses at maximum load. In this formula: P = maximum load; A = sectional area; S = yield-point stress from the coupon tests; $\frac{l}{r}$ = slenderness ratio; and, $\frac{1}{25\,000}$ = an empirical constant for steel columns with fixed ends. The Rankine formula was used for comparison, because it is well known and widely accepted.

The strengths of different columns cannot be properly compared merely on the basis of the stresses developed at the maximum load. It has been found[7] that for columns of the same slenderness ratio, $\frac{l}{r}$, the stresses at maximum load were approximately proportional to the yield-point stress of the steel from which the columns were made. The ratio of the average stress at maximum load on the column to the yield-point stress of the steel thus becomes a measure of the effectiveness with which the material in the column is used. The effectiveness ratio, that is, $\frac{\text{yield point}}{\text{column strength}}$, has been computed and is given in the next to the last column of Table 3. The highest ratio given is 0.954; the lowest is 0.879; and the average is 0.913. The maximum variation from the average is 4.4 per cent. The average effectiveness ratios for the riveted, continuously welded, and stitch-welded columns were 0.909, 0.921, and 0.900, respectively.

---

[7] *Technologic Paper No. 328,* Bureau of Standards, p. 85.

On the whole, it must be concluded that the maximum loads stated in terms of the yield-point stress of the material, determined at speed of testing stated, that is, the effectiveness ratios, were so nearly equal regardless of the method of fabrication of the columns, that no reliable distinction can be made between the merits of the three methods represented.

The ratio of the strength, $\frac{P}{A}$, computed by the Rankine formula, to the average stress at maximum load, is given in the last column of Table 3. The values of this ratio range from 84 to 92%, and the average is 88% of the maximum load.

11.—SUMMARY OF RESULTS

The results of this investigation may be summarized in the following eleven items:

(1) The largest slipping of plates shown by the measurements, was about 0.001 in. Even this may have been merely a difference in compressive deformation within the gauge length over which the measurements were taken. No weaknesses attributable to slipping of plates developed.

(2) Stitch welding caused shortening of the metal at sections through the welds and elongation at the edges of the cover-plates at sections midway between welds. In the stitch-welded columns, the strain lines appeared first on the sections through the welds, but none appeared in the welds or in the metal very close to the welds. In general, they did not appear between the welds except in the webs of the columns, where their formation apparently was brought about by initial compressive stresses set up in the cooling of the section after rolling.

(3) The points of first appearance of strain lines corresponded in position to the points of highest stress due to heating of the metal, as far as the stress due to heating could be determined.

(4) The average modulus of elasticity determined from the coupon tests was 29 300 000 lb. per sq. in., and that determined in the tests of the columns was 28 650 00 lb. per sq. in. The modulus used in computing stress from strain was 29 000 000 lb. per sq. in.

(5) In all comparable cases, the deflections were greatest for the continuously welded columns. There was little distinction as to deflection between the riveted and the stitch-welded columns. In general, the magnitude of the deflection corresponded to the magnitude of the initial departures from straightness. However, only one column of a kind was tested, and the differences in deflection are not large. Therefore, conclusions as to deflection should be used with caution.

(6) In Columns Nos. 3, 4, and 5, the bending stresses, and, therefore, the bending moments, were about equal at top, middle, and bottom. In the other columns, the position of maximum moment varied between top, middle, and bottom. Nothing in the tests indicated any marked advantage of either riveted or welded columns over the other as far as freedom from bending

moments is concerned, although the continuously welded columns seemed to be more subject than the others to initial deflection.

(7) In spite of its large initial deflection, Column No. 1, which was continuously welded, carried slightly greater maximum load than its counterpart, Column No. 1*BB*. The bending moments in this column, computed as the product of the loads times the deflections relative to the line of action, agreed fairly well with the moments computed from the measured strains. The deflections computed from the bending moments also agreed very well with the measured deflections.

(8) The limit of proportionality between applied stress and resulting strain occurred at stresses well below the yield point, but higher than the stresses at which strain lines first appeared. There was, however, a general correspondence between the stress at the limit of proportionality and that at which strain lines first appeared, and this suggests that both were influenced by the presence of initial stresses in the columns.

(9) The ratios of the stress at maximum load to the yield-point stress determined from the coupons were so nearly equal for all the columns tested, that no reliable distinction can be made between the merits of riveting, or welding, columns, either with continuous or an intermittent weld.

(10) Although the tests indicated the presence of initial stresses of considerable magnitude, introduced in the cooling after welding (and probably after rolling also), the maximum loads carried did not appear to be appreciably influenced thereby.

(11) The average stress at maximum load was about 15% greater than the strength computed by the Rankine formula, Equation (1).

ACKNOWLEDGMENT

This investigation was made at the Fritz Engineering Laboratory of Lehigh University for the McClintic-Marshall Company. Acknowledgment is made to that Company for permission to use the results in this paper and personally to Mr. G. L. Taylor and Jonathan Jones, M. Am. Soc. C. E., successively, Chief Engineer, for personal assistance and advice. The writers wish also to thank the following men then of the Department of Civil Engineering: R. J. Fogg, M. Am. Soc. C. E., for helpful suggestions; C. D. Jensen, Assoc. M. Am. Soc. C. E., for carrying out the test of the short column discussed in Section 5, and for furnishing interpretations of this and other parts of the investigation; and Mr. R. B. Morris, now of the Port of New York Authority, for valuable assistance in testing, and in compiling and interpreting the data.

APPENDIX

1.—Test Coupons.—A piece 1 ft. long was cut from each rolled section (plates, I-beams, and H-beams) before the columns were shipped from the fabricating shop. From this piece, four test coupons were taken for each cover-plate, six for each I-section, and eight for each H-section. These coupons were tested in tension for yield point and ultimate strength, and a few for modulus of elasticity. Hence, the yield point and ultimate strength of the steel reported for each column is based on the average of fourteen or sixteen coupons. As a result of this procedure the columns were 1 ft. shorter than the lengths originally designated.

Fig. 21 shows by cross-hatching the location and numbering of the test coupons cut from the various sections. The letter, *A*, when present, indicates that the coupon was taken from the core, that is, from the I-section or the H-section. The letter, *P*, indicates that it was taken from one of the plates. The final numeral indicates the location in the section. The coupons were arranged with a view of determining whether there were systematic variations of yield point throughout the section. All specimens were 1½ in. wide, except *A*1, *A*3, *A*5, and *A*7; and Columns Nos. 1, 1*BB*, and 2, which were 1¼ in. wide.

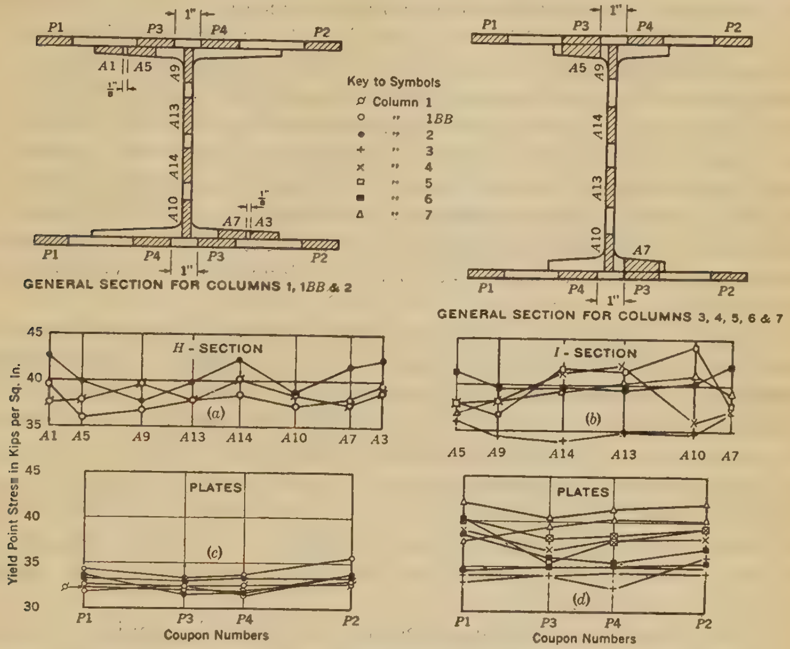

FIG. 21.—YIELD-POINT STRESSES DETERMINED FOR COUPONS.

The tests of the coupons were made in a 50 000-lb. testing machine in the usual manner for tension tests. The yield-point load was determined by the "drop" of the weighing beam in the tests in which the modulus of elasticity was not determined. In the modulus tests, the yield point was chosen as the load for which the strain indicated by the gauges showed a rapid increase with little increase in load. An extensometer with a gauge length of 2 in. was used in the tests for modulus of elasticity.

Considerable attention has been paid to the determination and weighting of yield-point stresses, because the strength of the column has been found to be more directly a function of the yield point than of the ultimate strength of the materials from which the column was made.

The yield-point stresses for individual coupons have been plotted in Fig. 21. The horizontal distances between points are proportional to the distances from center to center of coupons, so that a horizontal line on the diagram representing the average yield point for all the coupons for a given plate, will be weighted approximately according to the sectional areas represented by the several coupons. Fig. 21 (*a*) shows a tendency for the higher yield points to occur at the edges of the flanges and at the center of the web, and a lower yield point at the roots and at intermediate points on the flanges. However, examination of Fig. 21 (*a*) to Fig. 21 (*d*) indicates that the variation in yield-point stress for different locations in any section (either plate or core section) from the average, was not greater than about 2 kips per sq. in. An average not weighted for the area represented by individual coupons was used, therefore, as the yield-point stress for each section. The average yield points for the plates, however, differed in general from those for the corresponding cores, and it was necessary, in determining the yield-point stress for a column, to weight the yield point of the plates and that of the core in proportion to the area of each. This has been done, and the results are given in Table 6.

The yield points for the three **H**-sections show little variation from each other, while the yield points for the **I**-sections showed a somewhat greater variation, due to the low yield point for the **I**-section in Column No. 3. Among the plates the variation of yield point was greatest of all. Columns Nos. 6 and 7 were furnished considerably later than the other columns, and the yield points of the plates in these columns were considerably greater than the average for all plates. With only one exception, the yield point of the plates was lower than that for the core section in the same column. The maximum variation of an individual from the average of all the weighted yield points was about 7 per cent.

2.—Testing.—The following description of methods applies to Column No. 4 which was the first column tested. The others were tested in the same manner except for minor changes and improvements, as follows:

(*a*) Two-inch strain-gauge readings (Section *AA*, Fig. 6) were omitted from the other column tests.
(*b*) Four more gauge lines at Section *DD* in which slipping of the plates was measured, were added in the later tests.
(*c*) Gauge Lines 1, 3, 13, and 15 were added at Sections *BB* and *DD*.
(*d*) The testing of Column No. 1 differed materially from that of the other columns. This test is described in Section 9 of the main body of this paper.

The locations of the gauge lines on the cross-section of Column No. 4 are shown in Fig. 6. The gauge length at Section *AA* was 2 in.; at Sections *BB*, *CC*, and *DD*, it was 10 in. The gauge holes were drilled with a No. 54 drill (0.054 in. in diameter). Gauge Lines 5, 11, 17, and 23 in Section *BB*, were on the edge of the **I**-beam which formed the core of the column. Gauge Lines 5*b*, 11*b*, 17*b*, and 23*b*, had the same upper holes as Gauge Lines 5, 11, 17, and 23, but the lower hole for each of these lines, instead of being in the **I**-beam, was in the cover-plate close to the fillet weld. Equality of strain in

Gauge Line 5 with that in Gauge Line *5b*, would indicate that there was no slipping of the plate, but any difference in the strains between Gauge Lines 5 and *5b* indicates slipping of the plate relative to the I-beam, and this is true also with the other similarly placed gauge lines.

Before placing Column No. 4 in the testing machine, it was whitewashed with a mixture of white Portland cement and water, in order to make more evident the flaking of the mill scale (herein termed "strain lines") as the column came under stress.

After it had been placed in the machine, and before any load had been applied, provision was made for measuring the shortening over the entire length of the column at its four corners, and for measuring the center deflection relative to the ends. The instruments for measuring this shortening are here termed "compressometers" to distinguish them from the strain gauge. Each compressometer consisted of an Ames gauge and a distance piece. The distance piece was a $\frac{3}{8}$-in. steel pipe attached to the column 1 in. below the top, and of such length that its lower end bore against the plunger of the Ames gauge fastened 1 in. above the bottom of the column. Thus, the compressometers measured the total shortening of a column under load, except that which occurred within the 2 in. outside the gauge lenth. The distance piece was held in line by guides at about the one-third points of the length of the column. The Ames gauges read satisfactorily to thousandths of an inch. Each 0.001-in. total shortening corresponds to an average strain of $\frac{0.001}{182}$, or 0.0000055 in. per in. for the 182-in. gauge length, or to an average stress of 160 lb. per sq. in., using a modulus of elasticity of 29 000 000 lb. per sq. in.

For measuring the deflections, two fine wires were attached to the web of the column 6 in. below the top and 6 in. above the bottom, giving a span of 172 in. The deflection was read to the nearest 0.01 in. on scales attached to the column. The arrangement is shown in Fig. 22.

The column was tested in a standard two-screw testing machine of 800 kips capacity. As placed in the machine, the web of the column was in the plane of the longitudinal center lines of the screws. The bottom of the column was placed on a planed steel plate 3 in. thick, which rested directly on the bed of the machine.

This column was placed so that its top was centered accurately between the screws, letting the bottom of the column come where it would. Mounted on top of the column was a 3-in. plate, planed on both sides. On top of the plate and directly under the head of the compression block, were three pairs of wedges, each resting on a spherical bearing block. The three spherical bearing blocks, as placed on the 3-in. plates, outline an isosceles triangle, the apex block being centered over the web, 4$\frac{3}{8}$ in. north of the center line of the column. The other two bearing blocks were 4$\frac{5}{8}$ in. south of the center line of the column, 8 in. apart, center to center.

The compression head of the testing machine was then brought down until the wedges were nearly in contact with it; the wedges were driven in until they were equally tight as nearly as this could be judged; a load of 15 kips was applied to the column; and the compressometer readings were taken on all four edges of the column. This was followed by a load of 60 kips after which the compressometers were again read. If the difference in shortening on the four edges of the column revealed an eccentric loading, the compression head was raised, and the wedges were re-adjusted. This procedure was repeated until the shortenings measured by the four compressometers were equal within 0.002 in. in the 182-in. gauge length. The loading was then considered to be nearly enough axial to permit proceeding with the test.

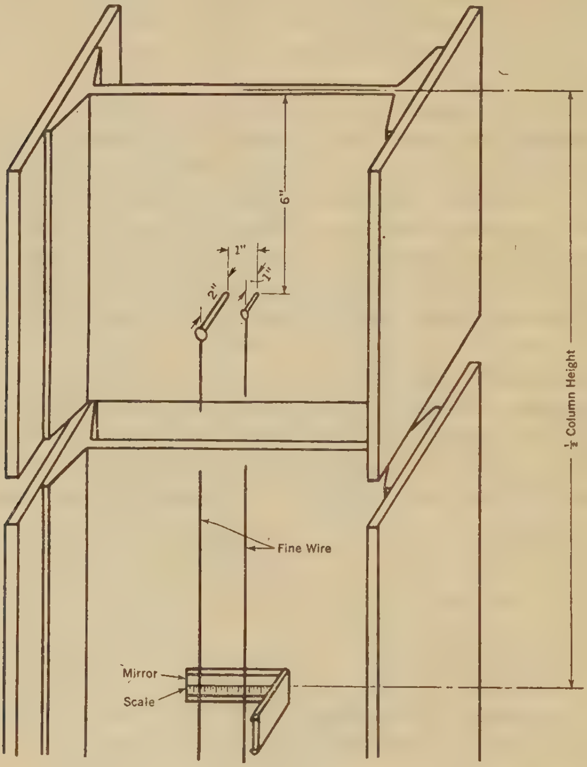

FIG. 22.—DEFLECTION APPARATUS.

The test was carried out with the increments of load shown in Fig. 18. Readings were taken on the compressometers and the deflection apparatus at more frequent intervals than on the strain gauges.

In the case of Column No. 4, after reaching the maximum load the operation of the testing machine was continued until the load had decreased to about 500 kips. Column No. 8 was not loaded to its maximum. In all other cases the loading was discontinued as soon as it was evident that the maximum load had been reached.

DISCUSSION

Raymond J. Roark,[8] Esq. (by letter).—The part of this paper that deals with the effect of welding on strains and stresses is of special interest to the writer, and it is with this subject that this discussion is concerned.

That the unequal heating caused by welding the parts of a composite member produces residual stresses is obvious, and many have expressed apprehension as to the possible effect of such stresses on the strength and stiffness of members so fabricated. Tests have been made for the purpose of securing information on this point, but few of them seem to have been planned so as to yield information on all three of the questions of practical importance, namely: (1) What total strains are produced by a given welding procedure? (2) What total stresses are produced? (3) What are the effects of these strains and stresses on the mechanical properties of the member as a whole? Thus, the tests made by Messrs. Slater and Fuller revealed the magnitude of the total strains produced and the effect—or absence of effect—on the mechanical properties of the columns; but, as the authors point out, they did not show what part of the total strain was plastic and what part represented elastic deformation accompanied by residual stress.

Some time ago the writer made tests designed to throw light on all three of the foregoing questions as they applied to the so-called "button" or rivet welding. The connection, in this type of weld, is effected by punching or drilling holes in one of the parts, placing it against another part, and filling or partly filling the holes with weld metal, as shown in Fig. 23. It is a convenient substitute for riveting, and is especially suitable for building up composite beams or colums of plates and channels.

The specimens used are shown in Fig. 24. The scheduled procedure in making up the specimens and the corresponding standard test pieces was as follows:

(1) Make six specimens from three bars; namely, Specimens *A* and *B* from one bar, Specimens *C* and *D* from one bar, and Specimens *E* and *F* from one bar.

(2) Make one standard tensile specimen from each bar.

(3) Anneal all material, including tensile specimens, after cutting.

(4) Drill Specimens *A*, *C*, and *E* for strain-gauge holes before welding and take strain-gauge readings before and after welding.

(5) Weld Specimens *A*, *B*, *C*, and *D*, thus:

(*a*) Weld Holes 1 and 5 (Fig. 24) and allow 30 min. for cooling.

(*b*) Weld Holes 3 and 6, and allow 30 min. for cooling.

(*c*) Weld Holes 2 and 4.

(6) Weld Specimens *E* and *F* without cooling and, in the sequence, Holes 1, 5, 3, 6, 2, and 4.

(7) Saw Specimens *A*, *C*, and *E*, as shown in Table 7, and then take strain-gauge readings.

---

[8] Associate Prof. of Mechanics, Univ. of Wisconsin, Madison, Wis.

(8) Make tensile tests with extensometer on Specimens *B, D,* and *F,* and on the standard tensile specimens.

(9) Make two additional specimens, *G* and *H*; follow the welding procedure outlined in Steps 2, 3, 4, 5, and 7, but anneal after welding and then test in tension.

FIG. 23.—SECTION *A-A,* IN FIG. 24.

Referring to Step 7, strain-gauge readings were taken on Specimens *A, C,* and *E* before and after welding, measurements being made on the gauge lines indicated in Fig. 24, and the total strain consequent upon welding was thus determined. The plates were sawed through as directed by Step 7 to ascertain how much of this strain was elastic. The front plates (with holes) were cut on the solid lines and the back plates (without holes) were cut on the dotted lines. A third set of strain-gauge readings was then taken on the uncut plate, and the elastic recovery thus revealed made possible an approximate calculation of the actual residual stresses introduced into the plates by the welding operation. Of course, only average stresses over the 2-in. gauge lengths could be determined thus, and it was possible to ascertain neither the maximum stresses nor the manner in which the stress varied from point to point.

FIG. 24.—TYPICAL TEST SPECIMEN.

The results of these measurements and calculations are given in Table 7. For convenience, the product of unit deformation and modulus of elasticity is given, rather than the unit strain. When this product is calculated on the basis of total strain (plastic and elastic), it is called apparent stress and when calculated on the basis of elastic strain, it is called actual stress. The terms are not exact, but it is believed that their significance is clear. In Table 7 these apparent and actual stresses are tabulated adjacent to the gauge lines where they were found to occur.

TABLE 7.—STRESSES MEASURED IN TEST SPECIMENS, IN THOUSANDS OF POUNDS PER SQUARE INCH

A study of Table 7 shows that: (1) The apparent stresses were very large; (2) the actual stresses were large in some cases, but were very much less than the apparent stresses, and had little if any consistent relationship thereto; (3) both apparent and actual stresses were highly irregular, showing considerable variation as between different specimens and as between different gauge lines on the same specimen; (4) in general, the actual stress in the intervals between welds was compressive in the rear plates and tensile in the front plates; and (5) as between the standard welding procedure, used in preparing Specimens *A* and *C*, and the "rapid" welding used in preparing Specimens *E*, the standard procedure appears to have caused much smaller apparent stresses and somewhat smaller actual stresses.

Five specimens were tested in tension. Three of these, *B*, *D*, and *E* were, respectively, similar to Specimens *A*, *C*, and *E*. The two others, Specimens *G* and *H*, were similar to Specimens *A* and *C*, but were annealed subsequent to welding. The quantities determined in the tensile test were the modulus of elasticity, proportional limit, apparent elastic limit, and yield point. In addition, the load at which the plaster wash began to flake off, and and the points at which such flaking first occurred, were noted. The capacity of the machine used was not great enough to permit the ultimate strength to be ascertained.

The results of the tensile tests, together with the results of tensile tests on standard coupons of corresponding material, are listed in Table 8, which is arranged to facilitate cross-reference between the actual and apparent initial stresses found in the several types of specimen and their tensile properties. It is apparent from these results, and from the stress-strain diagrams shown in Fig. 25, that the welding operation had little effect upon modulus of elasticity, apparent elastic limit, or yield point, but that it did cause a considerable reduction in the limit of proportionality, in comparison with either the annealed Specimens *G* and *H*, or the coupons.

It appears reasonable to assume that the low elastic limit of the welded test pieces was due to the presence of initial stresses, the material under initial stress reaching its elastic limit at a comparatively low average load. The rather well-defined break in each of the stress-strain diagrams would also seem to indicate that a considerable volume of material reached its elastic limit at the same time, and, therefore, must have been under an approximately uniform intensity of initial stress.

When the results of these tests are compared with those reported by Messrs. Slater and Fuller, it is seen that the apparent stresses are of about the same order of magnitude. The volume of weld metal deposited, and the corresponding heat input, was proportionately greater in the case of the tension specimens, and as would be expected the greatest strains caused were somewhat greater than those found in the columns. With the exception of a few values, however, the difference is not great, and it is of interest to note that the reduction in proportional limit caused by welding was about the same in the columns as in the tension specimens.

It would not be expected that the yield point in tension of a test piece as a whole would be affected appreciably by initial stresses, because the relatively large unit deformation occurring at and near the yield point permits an equalization of stress; but it might be supposed that, in the case of a column, any considerable non-uniformity in stress distribution would lead to buckling at a load less than that which the member might otherwise be expected to carry. The tests reported by Messrs. Slater and Fuller, however,

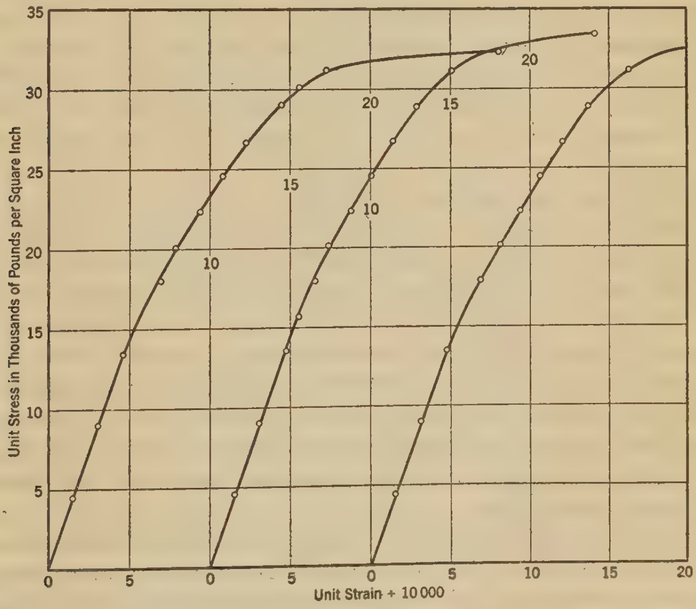

FIG. 25.—STRESS-STRAIN CURVES FOR WELDED SPECIMENS *B*, *F*, AND *D*, TESTED IN TENSION

fail to show any reduction in strength due to initial stress. It is to be noted, in this connection, that the columns tested by the authors were symmetrical with respect to the longitudinal axis, and that the welds also were symmetrically disposed with respect to that axis. This circumstance would tend to minimize both the tendency of the welding stresses to distort the column and their tendency to cause buckling due to local over-stressing. In a column in which neither the material nor the welding was symmetrical with respect to the longitudinal axis, both these tendencies might be appreciable. The welding procedure followed in preparing the tension specimens might have been expected to cause crookedness, and the uneven distribution of initial stresses would appear to indicate that there was some bending; but as far as could be ascertained by the eye the specimens were straight; there was no appreciable curvature either of the complete specimen or of the component plates.

On the whole, both the column tests and the tension tests appear to indicate that while welding may cause large plastic strains and fairly large stresses, and may appreciably lower the proportional limit, these effects are not necessarily accompanied by a reduction in strength. It would be of interest to know whether tests on columns of non-symmetrical section would bear out such a conclusion. It might also be of interest to ascertain the effect of the local over-stressing occasioned by welding on the "damping coefficient" of members thus fabricated.

LYNDON F. KIRKLEY,[9] JUN. AM. SOC. C. E. (by letter).—The commendable and complete analysis of steel column test data in this paper adds materially to the information already available on this subject. It provides needed experimental data on both welded and riveted steel column construction, and it is only to be regretted that the investigation could not have been more extended, especially with regard to the number of test specimens of each type as well as a wider range of core sections.

Although these tests will provide valuable information for a large part of light building construction, until similar tests have been performed on the much larger specimens used in heavy building construction engineers will not know much more of the mysteries of stress action and distribution in built-up steel columns. In heavy column construction it is not uncommon to find the heaviest of rolled **H**-sections buried beneath 2 to 4-in. cover-plates and surrounded by an additional arrangement of rolled angles and plates.

Until improvements have been made in the accuracy of correlation of stress analysis between these more complex column sections and the simpler types, as tested and described in this paper, not much will have been added to heavy steel column data.

Items (2), (3), and (10) under "Summary of Results," emphasize another problem of steel manufacture—the effect of heat upon the parent metal. The authors have pointed out in Item (2), the effects of welding upon the parent metal local to the point of the weld, which were caused by heating and cooling. In addition, the change in metallurgical structure of the parent metal local to the weld may be of some consideration, depending on the thickness of the two welded parts, the size of welding electrode used, arc voltage and amperage, and the rate of deposition of the weld. The effects of these conditions may vary with the thickness of the welded components and the consequent dispensation of heat of welding.

---

[9] Eng. Apprentice, McClintic-Marshall Corp., Bethlehem, Pa.

Variation of the chemical composition of the weld metal itself is also possible, depending on the degree of contamination by atmospheric gases during deposition. Mr. J. C. Hodge has pointed out[10] that by varying the efficiency of the protection, either by varying the nature and thickness of surface coatings and coverings, or by changing the length of the arc, the composition of the deposited weld may be changed at will. Thus, the nitrogen content may vary from 0.015 to 0.15, depending on the degree of protection. According to Mr. Hodge, other changes in chemical composition occur during weld deposition; for example, the carbon and manganese content are considerably lowered, which indicates the extreme oxidizing conditions within the arc. Furthermore, variations in chemical composition affect the elastic properties and the behavior under plastic deformation of the various weld metals.

The physical composition of a single ingot from which structural shapes are rolled may also vary from section to section throughout a specimen. Such variations manifest themselves in such natural defects of ingots known as piping, blow-holes, segregation, and crystallization, any of which may be present and vary in size and shape from microscopic to several inches in one dimension. These defects may or may not be corrected during subsequent working of the metal. Consequently, any one or a combination of these influencing factors may account partly for the variation of the yield point among the cover-plate and core-section coupons as mentioned by the authors in Section 1 of the Appendix.

The writer is fully aware that most of the points mentioned herein are of minor consequence with respect to strength of welded and riveted steel columns as finally produced, and that they are usually taken care of by adequate mill and shop inspections; yet he feels that they are deserving of mention and are points that contribute to the explanation of variations noted by the authors.

R. A. CAUGHEY,[11] M. AM. SOC. C. E. (by letter).—It occurs to the writer in reading this paper that it brings out the fact that there is much to be learned regarding the effect of welding in steel. There seems to be abundant evidence that permanent deformation is one of the results of welding. In Conclusion (2) the authors note that stitch-welding caused shortening of the metal at sections through the welds and elongation at the edges of the cover-plates at sections midway between welds. They also show that the moduli of elasticity of the columns as tested were lower than those obtained in coupon tests. It would seem that there may be a definite relation between these two phenomena; namely, that on account of unequal shrinkage in cooling, certain parts of the column sections received an initial compressive stress and other parts some initial tension. It is possible that when load was applied, the compression sections began to take compressive stress immediately, but that the sections in tension did not, until their initial tension had been overcome. Naturally, this would cause more deformation in the column than would exist if the entire section was acting; and, therefore, would give a lower modulus of elasticity for the compound section.

---

[10] *Engineering News-Record,* October 13, 1932.

[11] Prof. of Structural Eng., Iowa State Coll., Ames., Iowa.

As is stated by the authors, the two moduli do not differ radically, but the difference seems to indicate that initial stresses due to welding do exist and that they affect the modulus in the manner mentioned. Referring to Table 5, it will be noted that the moduli for the two riveted columns, Nos. 2 and 5, are 28 800 000 and 29 100 000, respectively, while those of welded columns (omitting Column No. 3 which seems to discount to some extent the writer's hypothesis) vary from 26 000 000 to 28 400 000. It should also be noted in connection with this table that the determination of the moduli, in cases of Columns Nos. 1, 6, and 7, is not entirely satisfactory to the authors.

Recently the writer had a little experience with the effect of welding on some small **H**-columns. It was desired to weld some small bars to the columns for the purpose of carrying clinometers to measure rotation of joints. In this case oxy-acetylene welding was utilized, and it is likely that a larger amount of metal was heated than would have been the case in electric welding. It did not take long, however, to find out that all strain-gauge holes near the welding had to be re-drilled, as the gauges would no longer fit into them. The welding process was abandoned in favor of tap-bolts.

If it was possible to do so, it would seem advisable to test some short lengths of compound sections, the specimens to be arranged in such a way that welds could be released without re-heating and stresses measured in various sections separately. It might be possible in this way to get some ideas as to initial stresses in the various shapes of the section. It might also be advisable to make some coupon tests from material adjacent to, or forming, welded connections in order to obtain data on possible change of moduli.

It is possible that changes in moduli may be caused by uneven flow of metal in various parts of a compound section after welding is completed. For instance, perhaps the metal at the junction of the web and flange of the **H** or I-sections of the columns under consideration would be somewhat more resistant to deformation than that in the outer ends of the plates riveted or welded to them. Fig. 16(*a*) seems to indicate that this is true in the tests under consideration.

The writer feels that more should be known regarding moduli changes and initial stresses caused by welding. Testing such sections as were tested by the authors, with provision for releasing welds and making coupon tests of material that has been welded, would probably give some information of that kind.

E. G. WALKER,[12] M. AM. SOC. C. E. (by letter).—The writer has read this paper with considerable interest and hopes that the comparison between riveted and welded structural steel work instituted therein will be continued. The paper evidences the considerable care and attention to detail that has been bestowed upon the work. It shows also that in the study of so uncertain an article as a composite structural steel column it is difficult to draw conclusions except after testing a large number of specimens. The investigation in the present case has been brought to a stage that enables one to judge the main structural differences resulting from the adoption of welding in place of riveting for built-up columns. It is insufficient, however, to enable definite distinctions between the two types to be formulated.

In the tests on the slipping of plates, no instance of undoubted slip of definite magnitude occurs. The fact that all the types tested behaved nearly alike does not enable logical conclusions to be drawn. Unfortunately, no tests are available in which slip actually occurred. Had there been, it might have been possible to deduce conclusions therefrom as to the relative resistance of the riveted and welded columns to slipping. Further experiments are necessary before it can be decided whether, if slip should actually occur in a riveted column, it would also take place in a corresponding welded column.

The use of welding, by reason of the localized heating of the structural material inherent in the process, introduces a new factor which does not have to be considered in connection with riveted work, where, although there must be a limited amount of localized heating around the rivet hole, this heating cannot extend to a sufficient volume of metal to influence stress distribution. The authors' investigations indicate that a certain amount of deflection is caused by stitch-welding and, therefore, there must be a corresponding amount of initial stress in the material. The question arises, as to whether, if heavier and more complicated sections than those used in the experiments were built up by welding, there might not be the possibility of developing initial stresses of such magnitude as to be a source of structural weakness. This does not seem likely, but it is a point that might well be investigated in the future.

The results of the deflection measurements are somewhat remarkable, in that they indicate a greater deflection in the case of the continuous welded column than in the other two cases. The writer would have expected the relative magnitudes to be the other way round, if there was any difference at all. It is quite possible that the limited number of tests available in this case have induced erroneous conclusions. The authors' strain measurements have led them to conclude that there was no definite slip in any of the columns. If that is so, there would not appear to be any reason for variation in the amount of deflection, and it is possible, therefore, that the conclusion may have been arrived at because the number of specimens of which records are available, is insufficient to enable true relative averages to be obtained.

The comparison of actual and calculated maximum loads given in Table 3, is of subsidiary interest. The values of the ratio of these stresses are thoroughly consistent, and the range of variation is not greater than one would expect. It follows, therefore, that the Rankine formula, with the constant used by the authors, gives definitely a strength lower than the actual strength of the specimen. An attempt made to adjust the constant in the denominator of Equation (1) which is the only constant that can be varied (the factor, S, being determined directly from the experimental results), was not altogether successful, and showed that, instead of being $\frac{1}{25\,000}$ as given, the figure should be about $\frac{1}{65\,000}$. This is inconsistent with the generally published values of this constant. It would appear that there is some other factor that should be considered in relation to the test results. Probably the degree of fixity of the ends of the columns when set up for test is the controlling factor.

---

[12] (Maxted & Knott), London, England.

M. Holt,[13] Jun. Am. Soc. C. E., and R. G. Sturm,[14] Assoc. M. Am. Soc. C. E. (by letter).—The deflections of columns with known eccentricities have been measured by the writers and have been found to agree closely with those computed by Fidler's formula:[15]

$$D = \frac{Pe}{P' - P} \quad \text{.........................} (2)$$

in which, D is the deflection of the column, in inches; P, the load on the column, in pounds; P', the critical load according to Euler, in pounds; and e, the total initial eccentricity, in inches.

A study of Equation (2) shows that the load-deflection curve for a column is curved from the first, thereby making the selection of a proportional limit from the load-deflection curve very indefinite. This probably contributed to the difficulty in selecting the proportional limits for the columns tested by the authors.

All columns have some eccentricity, which may be accidental and unintentional and may be made up of the sum of the effects of crookedness, non-homogeneity of material, uneven bearing at the ends, etc. The initial eccentricity will be large or small depending on whether the foregoing effects are all in the same direction or whether they counteract one another. Some of the columns reported in this paper were apparently quite straight while Specimen No. 4, for example, appears to have been quite crooked. The total initial eccentricity can be found from load-deflection data by plotting $\frac{1}{D}$ against $\frac{1}{P}$ and interpreting the data in the light of Fidler's formula which may be re-written as:

$$\frac{1}{D} = \frac{1}{P} \times \frac{P'}{e} - \frac{1}{e} \quad \text{.........................} (3)$$

---

[13] Research Engr., Aluminum Research Laboratories, Arnold, Pa.

[14] Research Structural Engr., Aluminum Research Laboratories, New Kensington, Pa.

[15] Fidler's "Treatise on Bridge Construction."

Equation (3) was first used in this form by Professors W. E. Ayrton and John Perry.[16] It may be noted that the intercept of this straight line on the $\frac{1}{D}$-axis is $\frac{-1}{e}$, and the intercept on the $\frac{1}{P}$-axis is $\frac{1}{P'}$. Information picked from the plotted data given in Fig. 18 of the paper is not sufficiently accurate to yield a reliable determination of the initial eccentricities of the specimens.

The fact that the bending stresses reported in the paper seem to have little effect on the maximum loads carried by mild steel columns is referred to as strange. It may be noted that in the cases shown, the bending stresses were relatively small and that if they are added to the ultimate strengths of the columns the total stresses would be quite close to the yield point stresses. Because of the definite yield point of the steel in the columns, the maximum stresses would not have an opportunity to increase to values appreciably above the yield strength of the material without excessive bending deformations. Thus, the loads giving maximum computed stresses equal to the yield strengths agree closely with the values obtained from the tests.

M. O. FULLER,[17] M. AM. SOC. C. E. (by letter).—The discussion of this paper has been a tribute to the memory of the late Willis A. Slater, M. Am. Soc. C. E., who was interested in the Society for many years, had contributed papers to its publications, and had taken an active part in discussion.

The tests described by Professor Roark are interesting in that they throw light on the total strains and stresses produced by a given welding process and their effect on the mechanical properties of the member as a whole. The fact that the apparent stresses from the tensile and compressive tests are about the same order of magnitude is very interesting as it may be of service to the designer in indicating the effect of the two kinds of stress upon welded connections.

The points mentioned by Mr. Kirkley are, as he states, of minor importance with respect to the strength of the welded and riveted steel columns, and are usually taken care of by careful inspecton.

Considerable is still to be learned regarding the effect of welding, and investigators are carrying on tests in this field. The work reported in the paper was only a small contribution to this subject, and the writer agrees heartily with Professor Caughey that much needs to be done to establish the relation between the initial tensile and compressive stresses set up on account of unequal shrinkage in cooling.

The question of crookedness in the test columns was one that had not been anticipated and for that reason the original column that was crooked was replaced by another made at a later date. The original column (No. 4) was tested simply as a matter of routine, as it was realized that one test was not sufficient to draw conclusions to any extent. Messrs. Holt and Sturm have explained the reason for the difficulty in selecting the proportional limit of the columns. A full report on tests of columns with known eccentricities referred to by them would be valuable.

THE MARTINEZ-BENICIA BRIDGE[1]

BY W. H. KIRKBRIDE,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. N. F. HELMERS, E. J. SCHNEIDER, M. F. CLEMENTS, JACOB FELD, AND W. H. KIRKBRIDE

SYNOPSIS

This paper contains a description of a double-track railroad bridge across Suisun Bay, California, constructed by the Southern Pacific Company. It replaces train-ferry operations across the Carquinez Strait between Benicia and Port Costa, Calif. The project includes other steel structures, in addition to the main bridge, and about 20 miles of railroad track equipped with signal and interlocking plants, on which track provision is made for grade separations for trains, and likewise for vehicular traffic.

GEOLOGY

Thirty-six miles in a northeastern direction from San Francisco, Calif., near the upper end of San Francisco Bay and connected to it by a narrow strip of water known as Carquinez Strait, is a body of water about 31 000 acres in extent. It is formed by the united waters of the Sacramento and San Joaquin Rivers flowing westward toward the Pacific Ocean and being retarded in their course by a range of mountains known as the Coast Range. The Carquinez Strait forms a connecting link by which the rivers unite with San Francisco Bay (see Fig 1). This inland body of water is known as Suisun Bay and, in former ages, covered a much larger area. After filling in the large inland areas now known as the Sacramento and San Joaquin Valleys, the two silt-carrying rivers began to deposit their sediments against the Coast Range, thereby reducing the area of this ancient sea and building up adjacent alluvial lands which are not equalled in fertility

In some cases inland bays along the Suisun shore line were filled with sediments containing a large percentage of vegetable matter. These bays are now virtually peat bogs, unstable in character. Such material is also found on the bottom of Suisun Bay.

---

Geologically, some interesting events have occurred in this vicinity. Evidence is found of former recurrent elevation and subsidence of the surface; pronounced earthquake faults exist upon which adjacent blocks of the earth's crust have moved in a northern and southern direction; and tremendous resistance to such movements has resulted in folds and distortion of the rock strata.

FIG. 1.—MAP SHOWING LOCATION OF THE MARTINEZ-BENICIA BRIDGE.

The hillsides bordering along the Carquinez Strait are broken and disintegrated to such an extent as to be very unstable, and slides are frequent, entailing unusual care and extra construction on the part of those engaged in the building and maintenance of railroads and highways in this territory.

EARLY RAILROAD DEVELOPMENT

The first railroads in California were constructed out of Sacramento, the first line being to Folsom. This was followed by the completion, in May, 1869, of the famous Central Pacific Railroad that formed a link in the first transcontinental line.

During the construction of the Central Pacific, a railroad was built in 1868 from South Vallejo to Sacramento, *via* Suisun, passing over a spur of the Coast Range and having a summit elevation of 315 ft. above sea level. In connection with this railroad a steamer line was operated from South Vallejo to San Francisco.

Next followed the construction, in 1869, of a railroad from Sacramento to Oakland, *via* Tracy, passing over the Altamont Summit of the Coast Range at Elevation 740 above sea level.

The railroad from Oakland to Martinez, along the southern shore of San Francisco Bay and the Carquinez Strait, was placed in operation in January, 1878, and, in the latter part of 1879, was also extended to Tracy. Thereupon, the steamer line to San Francisco was discontinued, and a ferry was established across the Carquinez Strait, connecting South Vallejo with the Tracy-Martinez-Oakland Line.

In December, 1879, a more direct low-level route between San Francisco and Sacramento being desired, the railroad passing through Suisun was projected directly across the marsh and peat lands on the north shore of Suisun Bay to Benicia.

A bridge across the Carquinez Strait or Suisun Bay was considered, but was found not economically feasible, and, therefore, a train-ferry system was established by which passenger and freight trains were transported from Benicia to a connection with the railroad on the south shore, previously referred to as the Tracy-Martinez-Oakland Line. This was accomplished by the construction of docks and car-ferry slips at Port Costa and also at Benicia, and by building the steamer, *Solano,* which remained in service until 1930 after fifty-one years of operation.

It is interesting to note that the designer of this boat made use of the principle of the truss bridge in designing the hull. In 1879, trains were small and rolling equipment was light; but notwithstanding this the *Solano* remained the largest car-ferry in the world up to the time it was removed from service. In 1914, as part of a second-track program, double-track car-ferry slips were constructed, and a second car-ferry, the *Contra Costa,* was put into commission.

It is interesting to note that the docks and slips were maintained with untreated piling from 1879 to 1919, a long life indeed for such original construction. However, in 1919, an infestation of marine borers (*teredo navalis*) destroyed the piling, and since that time creosoted piling has been used. The presence of the marine borers was due to the encroachment of salt water up the rivers, which, in turn, was caused by the use of fresh water for irrigation and by a long series of years in which the rainfall was sub-normal, thereby reducing the flow of fresh water through the strait.

The bridging of Suisun Bay or Carquinez Strait had long been under consideration. In the late Eighties newspaper discussions of the project were published and the Army Point-Suisun Point alignment was seriously considered by railroad officials. Later, a prominent bridge engineering company was requested to make studies, and following this, in 1904, during the time of the late E. H. Harriman, the late William Hood, M. Am. Soc. C. E., prepared plans for a bridge to replace the ferry system. Sundry locations were investigated, including one some distance up stream from the Army Point-Suisun Point alignment, and also several in the vicinity of Benicia and Port Costa, and others as far west as Vallejo Junction.

A series of test piles driven across the Bay showed that the bottom was of soft material, and that the depth to hardpan and rock strata was great; but it gave no clue as to the exact character of the bed-rock. It was decided to build a low-level bridge consisting of a swing bridge with a certain number of fixed spans and ballast deck trestle approaches. However, the application was denied by the War Department and the project was then dropped for the time being. Subsequently, the bridge studies were resumed and a crossing near Antioch was considered in connection with the extension of the Walnut Grove Line, but this route was rejected.

All routes crossing the Carquinez Strait proper were then likewise rejected because of the broken formation, slips in the hillsides, the nature of the terrain, the great depth of water, and, most important, the unfortunate necessity of crossing a well-established earthquake fault known as the "Southhampton."

Finally, in 1927, traffic conditions became acute and the Company faced the necessity of replacing the two existing car-ferries and buying a third, or of building a bridge. The bridge was then an economic necessity.

The two solid rocky points of land—one known as Army Point on the north shore of Suisun Bay, two miles east of Benicia, and the other as Suisun or Bulls Head Point near Martinez and adjacent to the tracks of the Tracy-Martinez-Oakland Line—offered the necessary supporting ground for the approaches and abutments, and permitted the solution of the railroad problem of providing connecting lines.

The Government demands a navigable channel 300 ft. wide for deep-draft vessels near the Martinez shore, but small craft, including fishing boats, use the entire width of the Bay. The presence of considerable soft mud on the bottom was known and the existence of hard rock below the mud was surmised; but the nature, extent, and depth below the water surface of such rock was not known. Proper data of the geological and earthquake fault condition were not of record. Accordingly, after a preliminary survey and a paper location of the route had been made, the services of geologists of experience and reputation were secured to report on the geological features, particularly with reference to the earthquake faults. This was followed by an exact determination of bed-rock conditions. For such purpose a row of diamond drill holes was put down across the Bay on the alignment of the bridge, as then conceived.

FIG. 2.—CROSS-SECTION OF SUISUN BAY ALONG CENTER LINE OF BRIDGE.

Bed-rock, consisting of alternate layers of shale and sand stone tilted up on edge at an angle ranging from 60° to 70° from the horizontal, was found at varying depths extending across the channel (see Fig. 2). Drill holes were carried well below the rock surface and the cores were carefully preserved and recorded.

A standard well rig, supported on a 14-pile staging, was used in drilling through the mud. A steel frame of angle irons was lowered through the water to the mud surface and through this a 10-in. well-casing extended to bed-rock, after which the diamond drill was used to explore the rock. A 2-in. rock core was secured. The nature of the mud and gravel overlying the rock was studied, and bearing values were determined. It was thus concluded that the bridge piers should be carried to, and founded on, the bed-rock.

The depth below low water to bed-rock ranges from 115 ft. near Army Point to 136 ft. near Suisun Point, at the location of the lift span. From these depths the rock slopes rapidly upward to the shore line on both sides. The depth of mud near Army Point is 59 ft., while the greatest depth of 101 ft. is south of Pier No. 13. The greatest depth of water is 57 ft. on the Army Point side. It is interesting to note that before the deposition of the present sediments the eroded channel was on what is now the shallow side.

The geologists reported the existence of two well-established major faults extending, parallel to each other, in a northwestern and southeastern direction. The "Southhampton" Fault is west of the bridge and passes under the ferry lanes between Benicia and Port Costa, and the "Green Valley" Fault is east of the bridge, 5 or 6 miles away.

In the Martinez hills various fault lines run in a direction angular to the major faults. The dip of the strata showed a reversal of direction, thereby indicating a folding of the earth's crust, local in extent, and also the development of a syncline. The direction of one of these fault lines was such as to present a serious question. Did it pass under the bridge? Unfortunately, the sediments in the Bay hid its true direction.

While there was some difference of opinion on the part of the geologists, they all agreed that the fault was not active and that any future movement of adjacent blocks along this fault line would be nominal. Its projection on a map shows that it might pass across the bridge tangent near the Army Point shore. On the other hand, the evidence showed that the fault might be a local shear or break in the formation caused by the folding of the strata, but which might not extend far into the formation upon which the bridge was located. This formation on the east was classified as "Chico-Cretaceous" and bedded against it on the west was a formation known as "Martinez," and bedded on the "Martinez" was a formation known as "Tejon." The folded and distorted strata seemed to be confined to the "Martinez" and "Tejon" formations.

However, if the fault line did extend beyond Army Point, it became important to determine its exact location, or at least to avoid the possibility of the most northerly deep-water pier (No. 19, Fig. 2) being placed on it. It was evident from the geological data developed that any slippage along the so-called Martinez Fault would cause the "Martinez" formation to be projected northward into and across the alignment of the bridge. It was decided, therefore, to put down additional diamond drill holes on the site of Pier No. 19. These core drillings, as well as those of all other diamond drill holes, were carefully studied by the geologists and paleontologists. Microscopic and other studies were made to determine from the fossils whether there had been any change in the rock formation. No such change was found, and the conclusion followed that the Martinez Fault did not extend across the bridge location and that the bridge foundations would rest solely on one monolithic block of geological formation, namely, the "Chico-Cretaceous."

However, for other obvious reasons, it was decided to design the bridge piers to resist earthquake vibration. Accordingly, they were designed with centers of gravity of mass as low as possible. Concrete specified for this purpose had a compressive strength of 2 500 lb. per sq. in., and a tensile strength of 400 lb. at the end of 28 days. It was further specified that the piers should actually be founded on bed-rock and that they should have 30 lb. per cu. yd. of steel reinforcement, placed so as to withstand earthquake shocks of an acceleration of 5 ft. per sec. per sec., which is twice the intensity of the San Francisco earthquake of 1906, and 1.5 times the intensity of the Tokyo, Japan, earthquake of 1923.

The superstructure was designed to resist similar shocks, the tops of the piers being widened and the base of the steel bridge seats being notched into the concrete in order to prevent the spans being pulled off their piers. In designing a pier structure of this kind to resist earthquake vibrations, a quick reduction from a large mass to a smaller mass is a source of weakness; likewise, a construction joint is undesirable and monolithic construction is essential. To secure this, as between caisson and pier shaft, and to overcome the difference of inertia of the two different masses, reinforcement rods extend upward from the outer walls of the caisson, pass through the distributing block, and curve inward and upward into the shaft of the pier (see Fig. 3).

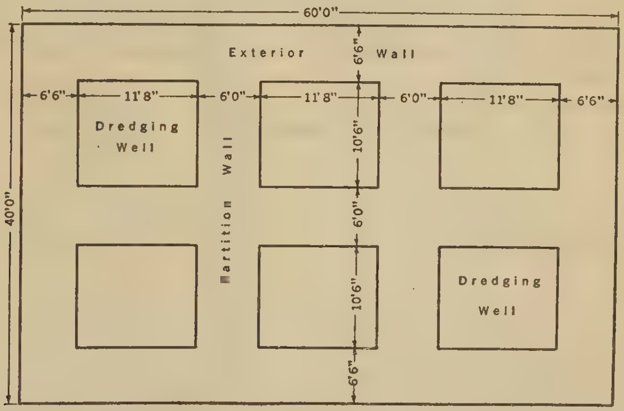

FIG. 3.—DIMENSIONS OF PIER NO. 13, MARTINEZ-BENICIA BRIDGE.

BRIDGE FOUNDATIONS

The substructure consists of two U-abutments, eight viaduct pedestal piers on land, and fourteen viaduct pedestal piers and ten truss span piers in water. Of the ten piers in water, eight are classified as deep-water piers, inasmuch as the rock bottom upon which they are founded ranges in depth below low water from 115 to 134 ft.

Pier No. 11 represents the shallow-water type that can be built by the open coffer-dam method. The size of the concrete base from which the pier shaft rises is 38 by 60 ft. It is oval in shape, with the top of the coping 16 by 49 ft., the side batter 24 on 1, and it was constructed within a steel sheet-pile coffer-dam, rectangular in shape.

Pier No. 13 is the deepest of the deep-water piers. The caisson for this pier was 40 to 60 ft. in cross-section and contained six dredging wells, 10.5 by 11.7 ft. in cross-section (see Fig. 4). The exterior walls were 6.5 ft., and the partition walls 6 ft. thick. The bottom of the caisson was of structural steel, shaped on the outside into a sharp cutting-edge, the interior partition struts conforming to the walls of the six dredging wells, being blunt on the lower surface to lend stability to the caisson during sinking operations

and to distribute the foundation reactions better. Except for the dredging wells, the caisson distributing block and pier shaft were of reinforced concrete. The dredging wells were filled with tremie concrete. The total volume of concrete in this pier is 12 283 cu. yd. The total weight of structural and reinforcing steel is 444 520 lb. Pier No. 12 (Fig. 5) is identical in design, except as to height. These two piers support the lift span and towers, and the adjacent spans.

The other deep-water piers are similar in design, except that the caisson dimensions are 38 by 60 ft. and the dimensions on top of the coping are 16 by 49 ft.

CONSTRUCTION

The construction of the part of the substructure on land followed the usual method of excavating to suitable rock foundation, placing forms, and pouring concrete; and the viaduct pedestals in water were constructed by driving coffer-dams of sheet-piling.

Piers Nos. 10 and 11 were constructed by the open coffer-dam method. Interlocking steel piles, 65 ft. long, were driven within timber falsework of piling on 7-ft. centers. Battered brace piles also were used, with two rows of 12 by 12-in. timber wales bolted to them. A single row only of sheet-piling was used in Pier No. 11. The inside bracing consisted of a crib or grillage of large, full length timbers, formed of 12 by 12-in. struts, 12 by 12-in. posts, and 12 by 24-in. wales tied together by 3 by 10-in. diagonal bracing, all securely bolted together (see Figs. 6 and 7).

The grillage was sunk nearly to bed-rock by being loaded with about 270 tons of steel rails. Mud and clay were dredged by means of a floating derrick barge, from which a clamshell bucket was operated.

When shale, sandstone, and bed-rock was exposed, about 1½ ft. of it was removed. The surface was then flushed clean, and concrete was poured "in the dry," the forms first having been set up inside the wales and sheet-piling. A mat 6 ft. thick was thus poured, after which the forms were set in to the prescribed section of 58 by 38 ft. and carried to Elevation — 36, where they were again set in to 53.4 by 22 ft. and carried to Elevation — 8. Above this elevation a pier of prescribed dimensions was constructed to bridge-seat elevation. One blow-out occurred while the coffer-dam was being unwatered, but the contractor overcame the difficulty without undue delay.

The construction of the deep-water piers presented a difficult problem. The depth of the water prevented open coffer-dam work, or the use of the pneumatic process. It was proposed, therefore, to sink caissons by the open-well dredging method. The depth of water, the existence of a maximum tidal fluctuation of about 10 ft., the swiftness of the current during the winter floods and at rip tide, and the softness of the underlying bay deposits, all made the launching and sinking of a timber crib difficult.

The contractors, to whom the foundation contract was awarded, proposed a unique method of sinking these deep-water caissons. The accepted construction involved, first, the driving of piles to support an octagonal-shaped platform. Upon this platform eight gallows frames equipped with hand

Sand Filling

Fig. 8.—View of Erection of Cutting-Edge of Caisson, Pier No. 12.

winches and with cables passing over sheaves set at the top of the tower were erected. By this apparatus a steel shell that may be likened to a bottomless oil tank, 81 ft. in diameter, was erected and lowered through the water into the mud, which it penetrated to a depth of 15 to 30 ft., depending on the compactness of the material. This shell was built up of circular sections, 10 ft. in height, which were bolted together, permitting the later removal of all but the part in the mud.

The top steel shell was above high water and was filled with suitable sand dredged from up the river. The area of land thus created permitted the exact staking out and fabrication of the steel cutting-edge of the caisson that was then sunk to rock (see Fig. 8).

After the steel cutting-edge had been erected, the reinforcement steel was placed and the concrete poured in successive lifts of 10 ft. in height. All this work was done above water, which permitted the caisson to be constructed of reinforced concrete of the desired quality and strength. Exact centering and orientation was thus assured.

When the first 20 ft. of concrete shell was completed, the sand was excavated from the six dredging wells by clamshells operated from floating derrick barges. The caisson gradually settled into the sand deposit and the underlying strata, as the excavation from the dredging wells continued.

At the time the concrete caisson was started, four well holes were put down within the steel shell, by which the exact elevation of the bed-rock was determined at four points, conforming to the four sides of the caisson. This information determined the proper height of the caisson prior to sinking and also the elevation at which to begin construction of a timber coffer-dam that extended from Elevation —20 to well above high water.

This coffer-dam (constructed of 12 by 12-in. timbers, drift-bolted, and properly caulked) was removable; temporarily, it rested upon, and was connected to, the concrete caisson by suitable tie-rods. The coffer-dam permitted pouring the distributing block (Fig. 3) and erecting the pier shaft from a depth 30 ft. below high water. It also effected a saving in concrete by the reduction of the large section of the caisson to the smaller section of the pier shaft, and created a temporary bridge seat or shelf which was used to support the steel bents of a falsework bridge span.

When the caisson was landed at or near bed-rock, and after the greater part of the material immediately above bed-rock was removed by hydraulic jetting and clamming, a deep-sea diver explored the bottom completely, telephoning the conditions existing within and under the caisson. He particularly noted the relation of the cutting-edge to bed-rock, and the amount of excavation still to be done.

In all cases considerable clay or gravel was found compacted under the partition walls and banked up against the cutting-edge. By means of the information thus furnished and by successive examinations the contractor was enabled to direct his jetting operations until the foundation area was reported satisfactory and in a clean condition.

The diver was able to supply accurate information as to the penetration of the cutting-edge into the foundation rock and in each case he brought up samples of the rock encountered. This was perhaps the first time a deep-sea diver was used at such great depth of water in open caisson work. It enabled the railroad engineers to verify the diamond drill borings, to know definitely the nature of the bed-rock formation, and to be assured that the bridge piers were actually resting directly upon the rock. Work was continued until a full bearing was secured and an interlocked connection established between the concrete steel cutting-edge and bed-rock.

Thereafter, the pouring of the concrete seal, consisting of tremie concrete, began. This operation consisted of lowering a tremie pipe, 12 in. in diameter, sometimes to a depth of 150 ft. The upper part consisted of a funnel-shaped hopper and the entire pipe was supported by a line leading to a hoisting engine, so that it could be lowered and raised as desired. A plug of excelsior was placed in the tremie pipe and the pipe was filled with concrete, about 4 cu. yd. being required.

Thereafter, the column of concrete was not permitted to break and as it was deposited in the hopper the pipe was raised a few inches to permit the concrete to mushroom out at the bottom. The process continued without interruption until the dredging well was sealed to the desired height, and, successively, the six dredging wells were thus filled. After a sufficient quantity of concrete was in place the lower end of the tremie pipe remained from 6 to 10 ft. below the surface of the concrete during the pour.

At the beginning of the work, in order to study the condition of the tremie concrete, and to assist in visualizing the interior of the dredging wells, the tremie concrete was first brought up to an elevation 30 ft. above bed-rock. After the concrete had hardened the water was pumped from the caisson, the sides were washed down, and the mud and laitance were removed, this deposit being usually about 1½ ft. thick. Samples were then broken out of the tremie concrete and tests made. In all cases a most excellent quality of concrete was found. Subsequently, being assured of the results obtained, the engineers permitted the tremie concrete to be brought, at one pouring, to near the elevation of the distributing block.

Within the recessed walls at, and resting upon, the prepared surface of the top of the caisson and the tremie-filled dredging wells, the distributing block was poured next. This was a large mass of reinforced concrete, 10 ft. thick, 50 ft. long, and 33 ft. wide (see Fig. 3).

The pier was completed by pouring the shaft to bridge-seat elevation in 10-ft. lifts. The wooden forms for this purpose were held in position by being bolted to the concrete section that was immediately below the section being poured.

The removal of the octagonal falsework, the pulling of the piling, the removal of the steel shell, and the dismantling of the timber coffer-dam followed in sequence after the pier was well above water. Such salvaged material was used again as work began on the next pier to be constructed. Fig 3, showing Pier No. 13, is typical.

The construction methods proved highly successful. In all cases the piers landed on bed-rock with only slight variation from the true center and inclination from the vertical. For instance, the caisson of the deepest pier

(No. 13) was off from true orientation by a southerly departure of 0.73 ft. and an easterly departure of 0.89 ft. The inclination from the vertical was 0.75 ft. in a height of 114.1 ft., which is equal to a batter of 150 on 1. Of course, even this slight error was not carried upward, as forms of the pier shaft were set to instrumental exactness.

Pier No. 12 may be used to illustrate the most accurate condition of placing. In this case the caisson departed from true orientation to the amount of 0.2 ft. northerly and 0.3 ft. westerly, the inclination from true vertical being only 0.14 ft. in 86.4 ft., which is equivalent to a batter of 600 on 1.

When one considers that these more or less unwieldy columns of concrete, with base areas of 2 400 sq. ft., and having a height in the one case equivalent to that of a 9-story office building, and weighing about 19 000 tons, have been set to the aforementioned accuracy, under the conditions found to prevail in connection with this work, the result appears to be marvelous.

To illustrate some of the construction difficulties the fact may be mentioned that at one time the caisson of Pier No. 12, was found to be out of level 1.3 ft. However, by confining the dredging to the wells on the high side, it was gradually brought back to a level position.

At another time when the steel shell was being set and sand was being placed at Pier No. 19, difficulty was encountered due to the tendency of the steel shell to settle to the north because the underlying strata was soft tule mud. The contractor righted the shell successfully, but due to the further settlement an additional 10-ft. ring of steel had to be applied. When next he attempted to fill the shell with sand, further settlement occurred on one side and the surrounding mud bulged upward.

Sometimes the caisson would fail to move downward, and as it was desired not to carry the dredging too far below the cutting-edge, small charges of dynamite were set off at the bottom of the dredging wells. These had the effect of causing the caisson to move. These instances illustrate the flexibility of the adopted method of sinking caissons.

SUPERSTRUCTURE

Fig. 9 is a view of the finished bridge, which is 5 603.5 ft. between abutments, accommodating two tracks spaced on 13-ft. centers. The elevation of the base of rail is 85.6 ft. above railroad datum, which provides a vertical clearance above mean higher high water of 70 ft. for the entire navigable distance of 4 050 ft. across the Bay. Provision also is made for a 328-ft. vertical lift span that will, when raised, clear mean higher high water by 135 ft. (see Fig. 10). The foregoing clearances are increased by 6.5 ft. when the tide is at mean lower low water.

The bridge is on tangent, except that spiraled 4° curves at each end extend outward on the viaduct sections. A length of 4 556.5 ft. of the bridge is on level grade, with approach grades of 0.45% on the north and 0.66% on the south end.

The superstructure consists of seven through truss spans of 526 ft. each, the distance center to center of piers being 531 ft., and also one vertical lift span,

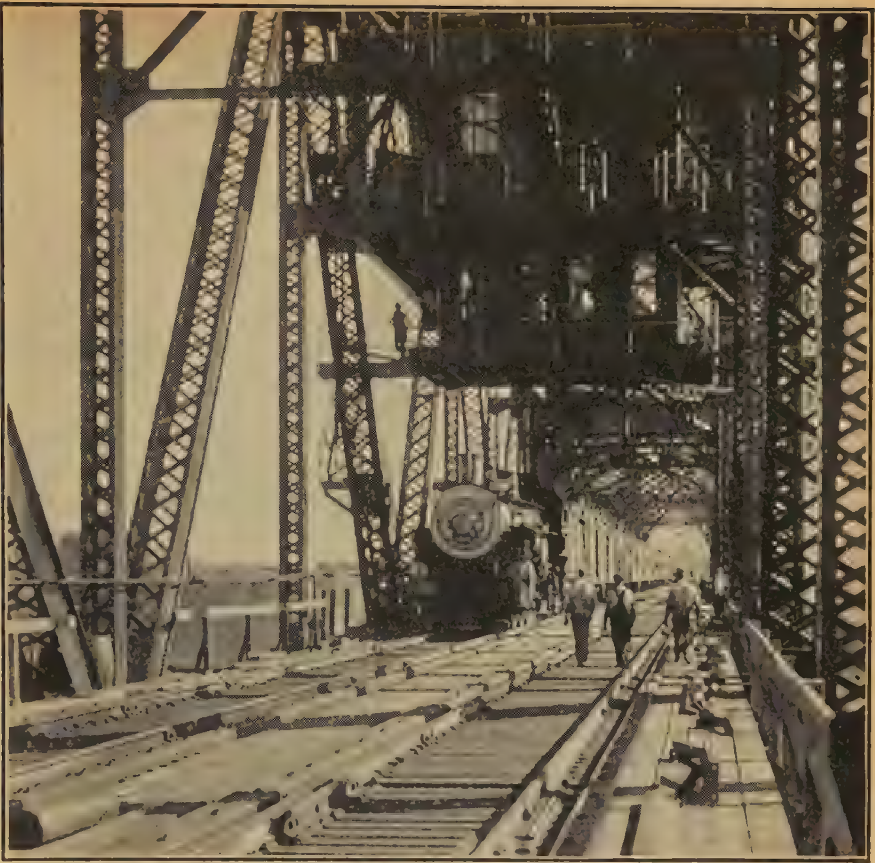

FIG. 9.—VIEW OF THE MARTINEZ-BENICIA BRIDGE, WITH TRAIN ON SPANS 12 AND 11.

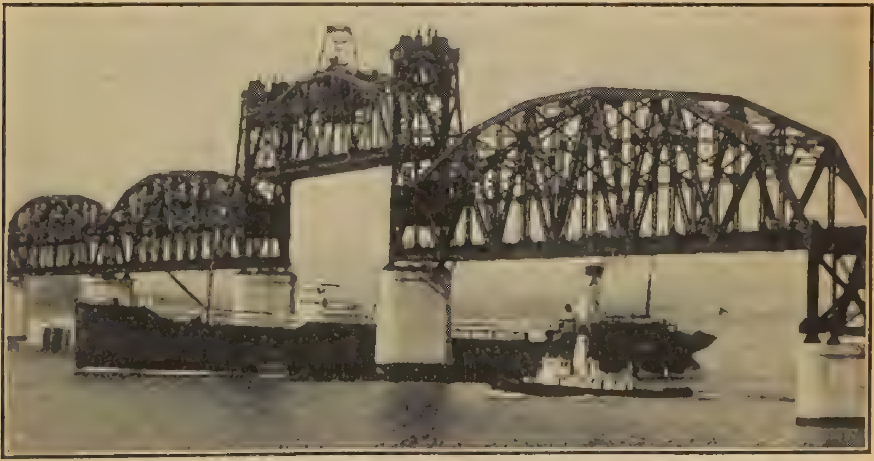

FIG. 10.—VIEW OF LIFT SPAN IN RAISED POSITION, MARTINEZ-BENICIA BRIDGE.

328 ft. long; one deck span, 504 ft. long; one deck span, 264 ft. long; a viaduct approach on the south end of five 80-ft. girders and four 40-ft. tower girders; and on the north end a viaduct approach of one 100-ft. girder and three 40-ft. tower girders.

Truss-span lengths of 526 ft. are not necessarily the most economical, but navigation interests are better served by spans of 526 ft., primarily to permit the passage of long barge tows without the danger of side-swiping of piers. After conference with the engineers of the War Department and navigation companies, the 526-ft. length was agreed upon.

The towers for raising the lift span are integral with the spans adjacent to the lift span and rise to a vertical height of 139 ft. above the bridge seat. The viaduct towers and girders are of the usual standard design.

Design.—The superstructure was designed for a minimum live load on each track equivalent to Cooper's E-90 followed and preceded by a uniform load of 7 500 lb. per lin. ft. of track. The uniform load was used or omitted at either or both ends of the concentrated load to give maximum stress.

FIG. 11.—DIAGRAM SHOWING PRIMARY DIMENSIONS OF LIFT AND MAIN FIXED SPANS.

This loading is 50% heavier than the present standard and with it stresses one-third higher than standard are permitted. In calculating maximum stresses due to live load and centrifugal force in girders and trusses of spans carrying two tracks, both tracks were assumed to be loaded simultaneously and 90% of the specified live load was used.

Silicon steel was used for the principal members fabricated from shapes, and carbon steel for the remainder, except that the tension bars in the lower chord, consisting of eye-bars, were heat-treated. The total weight of the

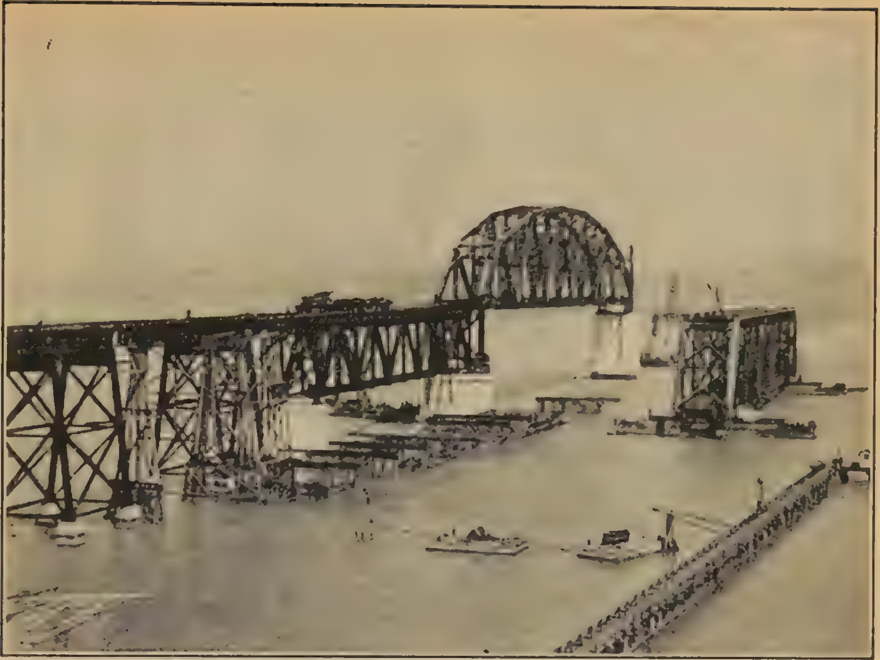

FIG. 12.—FLOATING SPAN 19 FROM FALSEWORK TRESTLE, MARTINEZ-BENICIA BRIDGE.

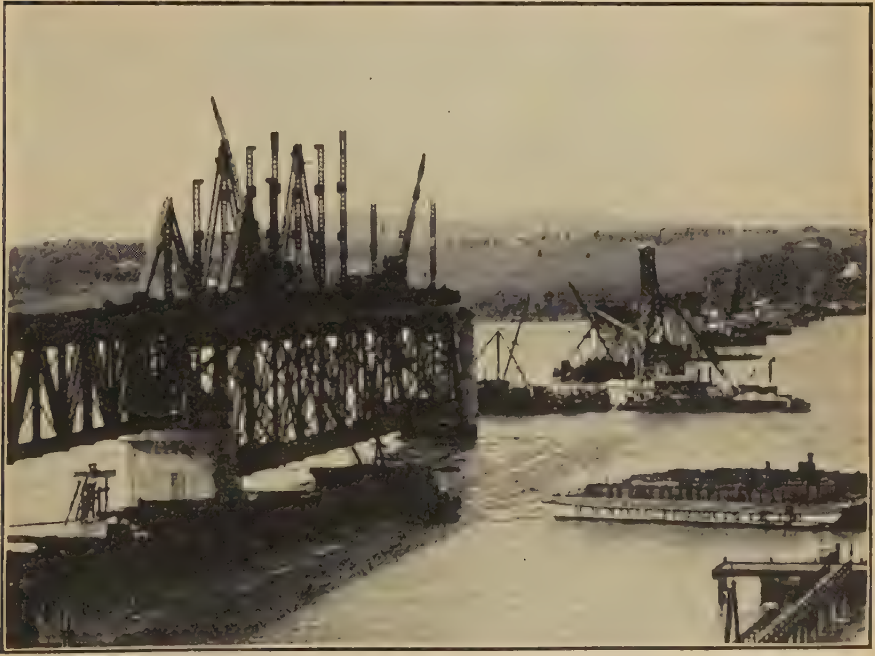

FIG. 13.—MARTINEZ-BENICIA BRIDGE: ERECTION OF SUPERSTRUCTURE AND CONSTRUCTION OF PIERS.

structural steel was 44 000 000 lb., comprising 25 000 000 lb. of silicon steel, 5 500 000 lb. of heat-treated eye-bars, and 13 500 000 lb. of carbon steel. The permissible unit stresses as used in the design were, as follows:

For axial tension in net section:

Carbon steel	21 300 lb. per sq. in.
Silicon steel	32 000 lb. per sq. in.
Heat-treated eye-bars	36 000 lb. per sq. in.

For axial compression in gross section:

Carbon steel.... $20\,000 - 70\frac{l}{r}$ (up to 16 500 lb. per sq. in.)

Silicon steel.... $30\,000 - 105\frac{l}{r}$ (up to 24 750 lb. per sq. in.)

The primary dimensions of the superstructure are shown in Fig. 11. The lower chords consist of heat-treated eye-bars; all other truss members are of rolled structural shapes. The lift span, shown in Fig. 10, is a riveted truss throughout.

CONSTRUCTION

Steel Erection.—Various methods of erection were considered, and it was deemed impossible to use timber piling successfully and economically owing to the depth of water, the softness and depths of the underlying mud, the swiftness of the current, and the height of the piers above water; nor was it deemed practicable to use the alternative method of "barging" the completed spans into position. An economical and satisfactory falsework method which avoided driving piling under the main spans, was adopted by the contractor. The steel was erected from the south or Martinez end, progressively working across the Bay to the Army Point end. The steel yard, therefore, was established at and near the south bridge-head, the railroad tracks, including the main-line tracks, being used for storage and switching purposes.

Proceeding from the abutment the tower posts and girders, comprising 560 ft. of viaduct, were erected by derrick car as far as Pier No. 10. Temporarily, the last pair of girders of the eastward track were used for a turnout approach to a falsework trestle that was driven immediately adjacent to and up stream above Pier No. 10 (see Fig. 12). This falsework trestle was provided for the erection of the falsework span, but the 264-ft. deck span was erected on it as a matter of convenience and was floated into its true position by means of barges and placed upon Piers Nos. 10 and 11. Next, Span 19, between Piers Nos. 19 and 20, was erected on the same falsework. This span, however, was used as falsework eight successive times in the erection of the remaining spans of the bridge. The procedure was as follows: After erection, Span 19 was floated from its falsework into position between Piers Nos. 11 and 12 (see Fig. 13) where it rested upon two temporary steel bents that extended to the shelf formed by the top of the caisson at Elevation — 20. These bents were secured to the pier shaft.

When the span had been set in place the elevation of its top chord was such that the necessary blocking to support the permanent span could be placed. Permanent spans were then built as follows: (1) Lay the floor system and lower chord; (2) erect the vertical posts, diagonal web members, and top chord; (3) jack up the completed span to release the falsework truss; (4) float the falsework span into position between the next piers; and (5) lower the completed span on its piers. To erect the lift span, the falsework span was placed back on the falsework bents and cut apart at a panel to make it of proper length to go between the piers.

After Span 18 was completed, the falsework span was finally floated into position as a deck-truss span for connection with the north viaduct approach.

Connecting Railroad Tracks.—The finished project included the construction of the equivalent of 20 miles of single track, and the reconstruction of 24 miles of branch line to main-line track.

On the north end the eastbound track descends on a 2.2% grade to a connection with the main line in a distance of 0.93 mile. This steep grade is permissible due to the fact that the train movement is descending from the high elevation of the bridge to the lower level of the existing main line, and a flatter grade is unnecessary and uneconomical. The reverse is true of the westbound movement.

The operating requirement is that the locomotive load be not reduced on full-tonnage trains moving from the north or east toward the west over the bridge. Therefore, it was necessary to build 3.64 miles of track on an ascending grade of 0.45% to attain the bridge elevation. This required an entirely new location, leaving the main line at Goodyear Station and developing a supporting grade line on the foothills to the north (see Fig. 14). The line crosses an arm of Suisun Bay, one of the inlets or marsh areas previously mentioned. The height of fill was 50 ft. and test wells proved the soil to be in the nature of peat, saturated with water, for a considerable depth. It was concluded, therefore, that it would be uneconomical to make an embankment, because the subsidence would be too great and the track unstable.

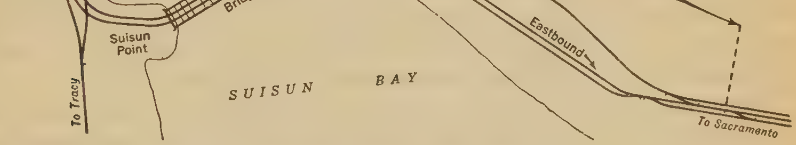

FIG. 14.—PLAN OF MARTINEZ-BENICIA BRIDGE AND APPROACHES.

The engineers were not without previous knowledge of the action of such marsh areas, inasmuch as the present main lines in this territory, for a distance of 10 miles, have been maintained under difficulties for years. The subsidence has been as much as 80 ft., even with the subgrade near the natural surface. Therefore, the choice was a steel viaduct, 1 860 ft. long. It consists of twenty-one 60-ft. girder spans and twenty 30-ft. girder tower spans, having concrete abutments and pedestal piers of concrete, each resting on 16 piles. The maximum length of piling was 80 ft. below the cut-off, which is below the water-table.

On the south end of the bridge the approach consists of a double track on a maximum 1% grade, extending in the direction of Oakland to Martinez Station. It was found impracticable, except at unjustifiable expense, to obtain an easier grade. However, 1% for eastbound traffic was not considered very objectionable as the grade would not restrict passenger trains unduly, and freights can be handled with "helper" engines, which will always be available, due to the large number of industries at Martinez requiring switching service.

Furthermore, most of the freight trains moving to and from San Francisco, and points to the south, will be handled over another approach, when the San Ramon Branch is reconstructed. This approach to the bridge will be on a 0.6% ascending grade eastward. Freight destined for Oakland (or the East Bay territory, as it is commonly called), and all passenger trains will still continue to move *via* Port Costa. A range of mountains extends in a north and south direction between the bridge and Oakland, making it necessary to follow the Bay shore on the north, or through Niles Canyon on the south, to reach either Oakland or San Francisco.

To facilitate such a movement, therefore, a second track, 4.4 miles long, has been constructed from the bridge to a connection with the existing double track at Port Costa. Part of this track is along the Suisun Bay shore and it has been riprapped as a safeguard against wave action.

The construction of the double-track aproach on the Martinez end involved some unusual problems. There, again, the engineers faced the problem of running track over marshland. The embankment was not as high as that on the north approach, however; the mud was shallower and below that there was hardpan. Other conditions also tended to make it desirable to construct a solid embankment. This embankment subsided during construction and the mud strata bulged outward, but excellent filling material was available economically and the job was accomplished without difficulty.

Miscellaneous Structures.—A concrete underpass was constructed through this embankment so that the westbound main line to Tracy could pass under the double track leading to the bridge. A 20-ft. vehicular subway was also constructed through the embankment.

Various other concrete structures, such as conduit boxes to handle numerous industrial oil pipes were constructed. Likewise, an overhead bridge was built to pass an industrial railroad over the main lines and sidings of the railroad (see Fig. 14). All structures were on pile foundations, driven into the mud strata to refusal, with the cut-off below water level.

The main lines are equipped with automatic block signals and in addition to the signals and interlocking plants an automatic train-stop system is installed on each side of the lift span. The control of the bridge-operating machinery, including the locks, rail locks, and signals, are handled by an electro-pneumatic interlocking machine with seven levers, provided with the customary mechanical approach and electric locking to insure that each function is operated in proper sequence and completely protected.

Each pier of the lift span is protected by a creosoted pile fender to permit the safe passage of sea-going vessels. This protection consists of a nose dolphin of fifty piles with two rows of pile spring lines leading to the piers. The spring lines are carried along the face of the pier by two rows of 12 by 12-in. timber fenders. The down-stream dolphin extends 46 ft. below the pier and the up-stream dolphin, 76 ft. above it. Protection is also provided at the other piers for smaller river craft.

All necessary navigation aids are provided and the top of the towers and the top chords of the bridge have flashing beacons for the benefit of air craft.

Concrete Tests.—Specifications for concrete required a strength of 2 500 lb. per sq. in. in compression and 400 lb. per sq. in. in tension within a 28-day period. After making exhaustive examinations of the available concrete aggregates, it was decided to require the cement to be fine enough that 85% would pass a 200-mesh sieve, and to use 3 lb. of diatomaceous silica per 100 lb. of cement, mixed with the cement at the cement plant. The concrete used in the piers, except the tremie concrete, was specified to be 1:2.5:5 mix by volume, or 1:2.4:4.6 by weight, with a water ratio of 0.9.

A well-graded crushed rock up to $2\frac{1}{2}$ in. in size, with sharp clean sand and 5 sacks of cement per yd. were used in this mix, and in the tremie concrete, $5\frac{1}{2}$ to $6\frac{1}{2}$ sacks per yd. were used, with $1\frac{1}{2}$-in. crushed gravel. The cement was placed in bins assigned to the particular job and after the tester approved the quality of the cement in it, the bin was sealed. Shipments to the job were made from this bin only.

Test cylinders were taken daily of the concrete poured. These were tested in the Railroad Company's laboratory for 7, 14, 28, 60 and 90-day curing periods. Greater strength was secured than was originally expected, as will be reflected by the following averages:

Age of test cylinders, in days	Ultimate compressive strength, in pounds per square inch
7	1 963
14	2 506
28	3 024
60	3 444
90	4 030

Because of the temperate climate, freezing and ice troubles were not encountered, but it was deemed necessary to consider the action of salt water on concrete. Therefore, that part of the concrete from a few feet below low water to a few feet above high water is formed of a rich 1:2:3 mix, using $1\frac{1}{2}$-in. rock aggregate. This concrete was poured dry and was subject to special spading and tamping so that a dense mixture was obtained. The surface was also treated to two coats of a coal-tar paint, selected after tests proved that the paint being used penetrated into the pores of the concrete.

Layout Work.—Ruling lines were established and caissons and piers were spotted by means of triangulation (see Fig. 15). First, a primary base line, 4 054 ft. long, was established and measured by an invar tape. From this a secondary base line was projected in a location near the south abutment, the triangulation stations of which were intervisible with other primary stations established on each side of the Bay. Another base line was established on the north side. Four triangulation stations, two on each side of the Bay, were thus established, by which all operations in connection with the sinking of the caissons and the erection of the piers were controlled with exact mathematical accuracy.

Grading Operations.—Extensive grading operations were required for the construction of the approaches. The contractor on the south end excavated and placed about 400 000 cu. yd. of material. The principal equipment consisted of two, 2-yd. steam shovels, operated by electricity, one 1-yd. drag-line, and one shovel operated by gasoline; and sixteen 10-yd. dump trucks, caterpillar tractors, and "bull-dozers." The contractor on the north end utilized dirt-moving equipment of ingenious design, his own development and manufacture. The principal equipment consisted of a 2-yd. Diesel steam shovel; 16-yd. heavy-duty dump carts and scrapers; and 60-h. p. caterpillar tractors. The dump carts were of all-steel welded construction; they were self-dumping and were mounted on caterpillar treads and hauled by caterpillar tractors. By means of this equipment about 500 000 cu. yd. of material was excavated.

CONCLUSIONS

The following unusual features of design and construction are worthy of special notice:

(1) The intensive examination into earthquake fault conditions and the design of bridge piers to resist earthquake shock;

(2) The creation of artificial islands of sand within steel shells by which the all-concrete caisson bridge piers were formed above water and sunk within the steel shells to bed-rock; and

(3) The temporary use of one of the permanent deck spans as falsework in the construction of the other bridge spans across deep water.

This bridge was placed in operation successfully on October 15, 1930. During the first 24 hours of operation the lift span was opened four times, and thirty-nine passenger and freight trains were handled over the bridge.

DISCUSSION

N. F. Helmers,[3] Esq. (by letter).—One of the outstanding features in the building of the foundations of this bridge was the constant use made of triangulation in measurements and layout. It is not unusual, of course, to resort to this method of locating piers for long crossings, but in this case a detailed system of signals was developed, permitting the use of triangulation to spot every pile in the falsework for each pier.

The base line was established approximately parallel to the bridge and ¼ mile down stream from the bridge site. From the two observation stations, all locations were given not only for the falsework, but for the sinking of caissons, erection of shaft forms, setting of anchor-bolts, etc.

In connection with pile-driving, signals to the driver were made by the use of a diamond-shaped target revolving about a center. One-half the diamond was white and the other half, red. The signaled direction to the pile-driver is indicated by the white half of the diamond target, which under ordinary visibility could be seen plainly without glasses, from any pier. For driving the falsework, the pile-driver was spotted at the intersection of two lines sighted from the two observation stations, the direction having been previously calculated to form such intersection for each pile as designated on the contractor's pile plan. To obtain the necessary degree of accuracy in turning the angles, each transitman turned from his foresight on the movable disk which was set to take care of the odd minutes and seconds of the arc. The vernier was not used. This method gave the location within a probable error of 1 in. The co-operation between the instrument party and the pile-driver crew was so good that a number of times 20 piles were driven in 2 hours under these conditions. Because of the swift current it was necessary then to stop and cap the driven piles in order to prevent their being broken off by excessive and continued vibration.

The main construction equipment of this work consisted of a heavy floating pile-driver, equipped with 90-ft. leads and using a 13 200-lb. double-acting hammer. The outstanding features of this machine was that, in addition to the pile-driving equipment, it carried a revolving derrick with a 75-ft. boom and had an unusual number of engine drums and winch-heads. The machine carried four 2 700-lb. anchors, each of which was handled on wire rope and operated by steam. In addition, it could carry two or more bow and breast lines; it also carried two heavy jet pumps, delivering water at 250-lb. pressure, through 2½-in. jet pipes.

Because of the need of pulling the falsework piles after the pier was completed, the machine was not rigged for batter piles, which were driven by out-hauling the hammer instead of battering the leads. It may be of interest to note that the piles in question ranged in length from 100 to 125 ft., with a 24 to 26-in. butt, and a minimum tip of 10 in.

---

[3] Siems-Helmers, St. Paul, Minn.

The second important item was a 2-yd. floating concrete plant with a 104-ft. tower. It was equipped with its own "whirley" derrick for feeding the bins, as well as a bow derrick for handling spouts and tremie pipe. This machine handled tremies as long as 160 ft. for under-water concrete. Its normal capacity was 60 cu. yd. of concrete per hour. It was equipped with weighing devices to permit rapid change in aggregate proportions. It also carried extra engines to handle four anchors on wire-rope lines.

In addition to the foregoing there were two heavy floating derricks, five stiff-leg derricks erected on the falsework of each main pier, five tugs, a locomotive crane, a pump barge, a complete machine shop, and a number of deck lighters. The cement was handled in two heavy barges, housed, and provided with an inclined belt conveyor, power-driven, which delivered the cement on the platform back of the mixer on the concrete plant barge.

Practically all the machinery used was operated by steam, with oil as fuel. The tugs were operated by Diesel engines. All the plant used on this job was the property of the contractor.

Pile-Driving.—At each of the eight main piers, as soon as the first falsework piles were driven, a carefully detailed report of its behavior was wired to the contractor's consulting engineer, who estimated the depth to which the steel shell would sink and determined whether or not the mud should be removed from the inside of the shell before placing the sand filling. These studies and recommendations proved wonderfully accurate in forecasting the behavior of each caisson.

One of the important items in handling this job was the behavior of the mud on the bottom of Suisun Bay. It has been demonstrated that ordinary river silt gives sufficient bearing to be entirely satisfactory for the method used. Only a slight settlement occurred at Piers Nos. 13 to 18, where ordinary river silt was encountered.

When falsework piles were driven at Pier No. 12 a very soft bottom was found. The 100 to 110-ft. pile sank 43 ft. under the weight of the hammer and pile, and moved 5 ft. under the last ten blows. Both shell and caisson showed some movement under these conditions, and when the dredging in the caisson had gone through the sand-filling and had relieved the mud under the cylinder of sand, both the steel shell and caisson listed so much that, at one time, the caisson was 18 in. out of plumb and the shell nearly 8 ft. At certain times the dredging would be 5 ft. below the bottom of the dredging wells on the high side (which was the maximum permitted), and as much as 12 ft. above the bottom of the cutting-edge of the low side. The caisson was landed within 6 in. of the correct theoretical position.

The softest ground of all was at Pier No. 19. The material was described on the original drawing as "blue mud with vegetation" and the falsework piles used were from 120 to 126 ft. long, extending practically to the rock. From 100 to 110 ft. of shell was used in the sand island for this pier. The weight of the sand island pushed the soft material from under it, moving a part of the falsework upward with the flow. Instead of settling uniformly at all times the shell and its sand-filling settled spasmodically, sinking 3 or 4 ft.

on one side and then leveling itself in the next few hours. On April 22, 1930, this shell was 7 ft. out of level.

An attempt to cure this by loading with sand and jetting on the high side was practically unsuccessful, but by dredging for 24 hours on the high side, the shell was brought to within 1 ft. of level, when the dredging was stopped. Additional sand was then added to get it still nearer level. The reason for this procedure was to obtain most, if not all, of the settlement before work on the caisson or pier proper was begun.

An interesting detail of the method used was that the maximum weight is secured at the start; that is, when the sand-fill was completed and 25 ft. of caisson added. From that point the weight of the sand removed and the water displaced by the concrete outbalanced progressively the increased weight of the concrete caission.

Under this method of sinking, the sand between the steel shell and the caisson can always be removed, thus relieving skin friction and giving the greatest weight desired to permit rapid sinking. Under normal conditions a caisson can be sunk at the rate of 10 ft. in a 4-day cycle, and, at times, this was reduced to 3 days.

E. J. SCHNEIDER,[4] M. AM. SOC. C. E. (by letter).—As long ago as 1910, the writer saw designs of a proposed structure across Suisun Bay. Nothing really developed until about 1928, when the psychological moment seemed to appear, and it was apparent that the two car-ferries would soon have to be replaced.

The Engineering Department of the Southern Pacific Company was ordered to make an estimate showing that it would be possible to build the bridge. For preliminary purposes, more than twelve estimates were made of steel for various combinations. Single-track, double-track, and gauntlet-track were considered, as well as high-level and low-level. The "low-level" requirement was that the under-clearance would be 20 ft. above mean higher high water, and the "high-level," 70 ft. Studies were made to determine whether a highway should be built in connection with the bridge, and estimates were prepared with and without the highway, as well as for the construction of the highway at some future time. Furthermore, carbon, heat-treated, and silicon steel were considered in connection with continuous, cantilever, and simple spans. This gives an idea of the various combinations under consideration.

The final choice was for a typical span consisting of a through Warren truss designed to carry a double-track load equivalent to E-90, followed and preceded by a uniform load of 7.5 kips per lin. ft. The total weight of the steel was 42 000 000 lb., of which, 25 000 000 lb. was silicon steel used for the main built-up truss members, floor-beams, and stringers; 4 000 000 lb. of heat-treated eye-bars for the bottom chord of the fixed truss spans; and the remaining 13 000 000 lb. was ordinary carbon steel.

Although it is customary to test to destruction, one or two eye-bars from every heat, the question was asked, "How do we know that the ones that are not tested are all right?" This was given much consideration because of the size of the bridge and the amount of money involved, and it was finally decided that each bar should be proof tested. As a result, the 1 807 bars were tested in the full-sized testing machine, at Ambridge, Pa., and every bar came well within the required limit. This confirms the opinion of the engineers of the fabricators who have always maintained that the eye-bar is one of the most dependable sections in a structure.

---

[4] Contr. Mgr., Bridge and Structural Dept., Columbia Steel Co., San Francisco, Calif.

Mr. Kirkbride has explained why this particular location was chosen. The type of superstructure was selected because of economy of design, ability to resist earthquake shock, simplicity of repair, and simplicity of erection.

When the preliminary studies were made, it was first thought that a span of approximately 408 ft. would be an economical length; but the economical curve was about horizontal between 400 and 500 ft., and the question was settled when the War Department ruled that the distance between center to center of piers should be 530 ft. This decision was not reached, however, until the Army engineers had made several tests of long tows in the vicinity of the bridge where swift tides and cross-currents frequently occur. Their experiments indicated that a longer span was necessary to provide ample clearance and to prevent long tows from being "side-swiped." The War Department ruled on a 70-ft. under-clearance from mean higher high water for all except the lift span. This means that all river craft can pass under the bridge and only sea-going vessels will be required to use the Government channel where a lift span is provided with 300-ft. horizontal clearance and 125-ft. vertical clearance above mean higher high water.

The difficulties encountered in building the foundation due to the strong current and deep water and great depth of solid rock have been described in the paper. If these factors could have been avoided, the erection would have been much simplified.

All the through spans have the same panel length. The deck span, which Mr. Kirkbride has mentioned as doing so much work, has the same panel length, except that the two end panels were fore-shortened so they would go between the piers instead of resting on them. Reference was also made to the shelf or offset at the top of the caisson proper which was at Elevation —20 below mean lower low water. This is one of the important details required in connection with the erection of this falsework span as this shelf supported a temporary steel bent on which the deck falsework span rested. The erection of the steel began from the south end and in building temporary falsework and turnouts, as much as possible of the material going into the main span was used temporarily. Two 80-ft. girders were used, which later were incorporated in the south approach; and two panels of through 506-ft. deck span were also used temporarily in erection.

The barges for floating operations were those originally designed and built for the erection of the Carquinez Highway Bridge about 7 miles down stream from the Martinez-Benicia Bridge. They were 40 by 130 ft., with 10-ft. depth, and had a capacity of 1 000 tons. When used on the Carquinez Bridge they carried a maximum load of 800 tons. When loaded to

1 000-tons capacity they had a free-board of 1.5 ft., and extra waling strips were provided on the side so that the deck would be kept dry in case of rough weather.

The first span was floated on February 28, 1930. Advantage was taken of the low tide when the barges were placed under the span. Shortly after noon, the floating was completed, and the span was resting on the temporary bents between the piers. The bents supporting this span were of sufficient length so that the span when erected on this falsework would be about 3 ft. above its proper elevation. Hydraulic jacks were used to take care of any adjustment which might be necessary.

When the lift span was swung, the falsework span was returned to the temporary dock where it originally rested and was re-assembled to the remainder of the span. As the lift span was only 300 ft. long, only eight of the twelve panels of this deck span could be used.

It was not quite so easy to land the deck span in its final position as might be expected because the north bank is not at right angles to the track. The rock-fill embankment is at an angle of about 45° and, therefore, it was not possible to warp the north barge alongside the pier as in deep water. The plan adopted was to warp the span in on a skew so that one shoe could be placed in its permanent position. This shoe rested on a turn-table center and the span revolved about this point. A falsework platform with a system of rollers was provided to accommodate the other pedestal. As the weight was transferred to this falsework platform, the inner barge was removed and the span swung into place as the outer barge was warped into its proper position.

M. F. Clements,[5] M. Am. Soc. C. E. (by letter).—In Conclusion (2) of his paper, Mr. Kirkbride lists the artificial "sand island" as one of the unusual features worthy of special notice.

The use of islands for the lowering of concrete or timber caissons is not new. The first use that has come to the writer's attention was a record of construction of a bridge foundation at Pittsburgh, Pa., in the Eighties. The Romans used mounds of rock or artificial islands on which bridge piers were built. They also used timber caissons, and it is reasonable to assume that they used the timber caisson and artificial islands in combination. The use of the rigid steel shell to enclose sand to form artificial islands is new and was suggested by the writer to the contractor, and his proposal to the Railroad Company for the piers at the Martinez-Benicia Bridge was submitted as a substitute for floating creosoted timber caissons.

The plans submitted to contractors in the invitation for bids were examined and the difficulties of building a floating caisson with a high tide, a fast current, and a very soft underlying material, were noted. The high tide and fast current would naturally prevent the seating of a floating caisson, as there would be a continual washing away of underlying material. This wash would then increase the area of floating caisson exposed to current; it

would require more anchorage; and would make it more difficult to locate the caisson accurately. To overcome the foregoing natural conditions the writer recommended the artificial island method as being most suitable for doing the work.

It came to be known on the work as the "sand island" method. Among the advantages in its use, the writer lists a number, as follows:

(1) The element of danger that enters into the handling of large, expensive floating caissons is taken by the lighter, less expensive, preliminary shell, thereby reducing the risk in handling deep-water, deep-foundation construction work. The writer considers the safety element of the use of the "sand island" method to be the most important, and it was the principal reason for recommending its use on the Martinez-Benicia Bridge.

(2) The construction of an all concrete caisson entirely free from the use of timber permits actual contact of the concrete caisson walls and the concrete placed in dredging wells. In salt water infected by teredo or other marine borers, a wooden floating caisson must be protected by an outer layer of creosoted material, which adds to the cost of that type of construction.

(3) Concrete was poured above water where the mixture could be controlled and the deposit made in the dry. In comparison with the floating caisson, this is a distinct advantage in that a floating caisson cannot be made water-tight; therefore, tremie concrete had to be poured, and it would be impossible to obtain 3 000-lb. concrete, such as cited by Mr. Kirkbride, on account of the presence of water in the wall form of the caisson.

(4) With the "sand island" method the bottom part of the caisson is substantially supported by the sand, and high strength reinforced concrete can be made. The structural steel cutting-edge is merely a metal covering which is comparatively inexpensive; whereas, with the floating caisson, the cutting-edge is a rigid frame supporting superimposed water-tight compartments in which concrete is placed. The cutting-edge of a floating caisson is of necessity of greater weight and cost than one used on a caisson constructed on an artificial "sand island."

(5) The structure was spotted accurately over its final location at the beginning of the work.

(6) The caisson was controlled during the sinking process for the entire depth. The sand acting as an equalizer of frictional value for the different classes of material, penetrated below the natural ground line. At this bridge there was no sudden sinking as the caisson entered the mud below the sand in the shell.

(7) The caisson could be controlled in landing on the bottom. At the location of the bridge there was a fluctuation of tide amounting to 10 ft. and a velocity of current of 5.8 miles per hour in either direction, due to ebb and flow tide.

(8) The "islands" weigh the same as the caissons which pass through them and the action of high water, winds, waves, and tides has no greater effect than they do on the permanent piers.

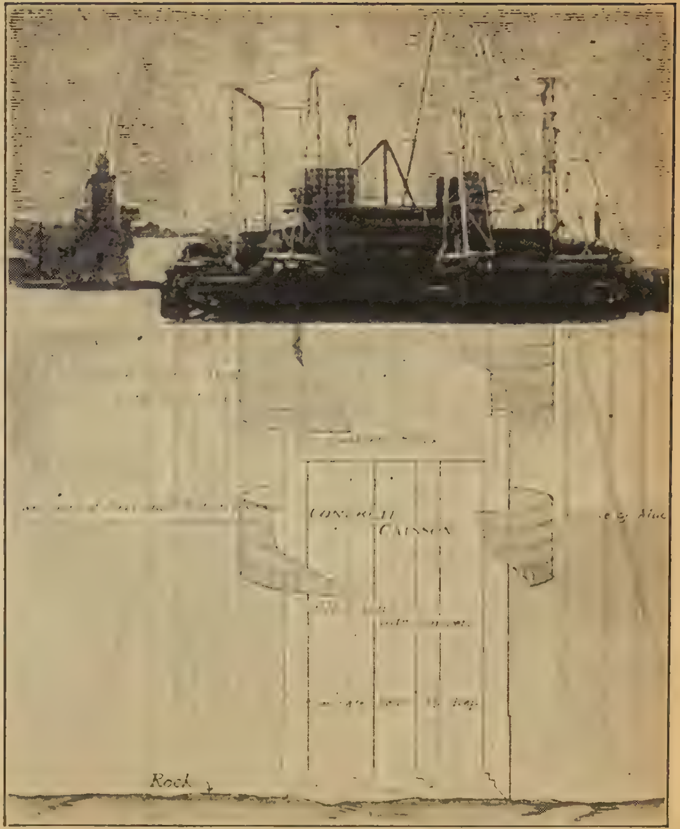
FIG. 18.—SINKING CONCRETE CAISSON THROUGH STEEL SHELL AND ARTIFICIAL SAND ISLAND.



CONCRETE CAISSON
Rock

FIG. 19.—REMOVING STEEL SHELL FROM ARTIFICIAL SAND ISLAND.

(9) The method results in a marked saving in cost that varies in amount by the extent to which shells and falsework can be re-used. The actual costs resulting from the construction of "sand islands" were exceedingly close to the estimate.

(10) Speed of construction by the "sand island" method is the result of a better co-ordination of the work. The speed of sinking the caisson depends upon the speed of its construction and this can be handled with greater speed on a rigid rather than a floating structure. The Martinez-Benicia Bridge was actually completed before the anticipated date.

(11) The method reduces the amount of floating equipment required and can be applied with a minimum amount of fixed equipment.

(12) Steel sheet-piles have been used for enclosing sand in shallow water, but are not of sufficient strength for the greater depths, and had their use been attempted at the Martinez-Benicia Bridge, it probably would have resulted in the loss of two islands and caissons.

(13) The "sand island" method eliminates the necessity of constructing launching ways and providing anchors and anchor barges, which are used in the floating type of caisson.

As a matter of information, it is well to call attention to the predicted movement of islands and caissons during sinking. This was done by analyzing the data obtained on the pile-driving during the construction of the falsework. The shells were assembled on I-beam supports and lowered into the mud. As a matter of fact, the shells were lowered to an elevation 5 ft. above the mud line and then, with all lines released, it was permitted to drop 5 ft. to force a penetration into the mud. The analysis of pile-driving for the purpose of determining the depth to which the steel shells would sink into the mud, was made with surprisingly accurate results. Some difficulty was experienced at the last deep pier (No. 19, Fig. 2), and after the pier had been landed on bed-rock, it was evident, in the light of experience, that all the action of the caisson could have been predicted and all delay avoided.

Another lesson was learned from estimating the possible sinking of the shell into the mud as the result of analyzing the action of the test pile. The value of the pile to support load is both in terms of bearing on the tip and friction on the sides. A pile of known size and approximate weight was lowered until its tip touched the mud. It was then released and the penetration from its own weight noted. A hammer weighing approximately 13 kips was placed on the pile and its further penetration noted. The bearing and friction as determined by these tests were applied to the bearing area and sides of the steel shell and the final depth to which the shell would be sunk, was determined. In most cases, the depth was predicted to within 1 ft. However, that is not so important as the fact that the prediction was made for a shell, the bearing area of which was one hundred and fifty times the bearing area of the pile.

These computations were based on ultimate values. In other words, the ultimate value of the mud or earth in bearing for the larger area was determined by the smaller area. The writer believes that tests made on soils on small areas will give fairly accurate bearing values for larger areas. This has been a disputed point, but the results of the tests of pile-driving at the Martinez-Benicia Bridge tend to prove the statement.

As a result of the experience at this bridge, it is the writer's opinion that deep piers can be placed by the "sand island" method in tidal waters under adverse conditions of high winds and waves, using circular shells 400 ft. in diameter in water 150 ft. deep.

It may appear in first analysis that the cost of all large sizes is excessive, but the safety factor outweighs all disadvantages. It can be used where the abnormal conditions, due to wind and waves, make a floating caisson dangerous.

Under the heading, "Construction," the author had described the steps involved in the artificial sand island method. Fig. 16 is a view showing piles driven to support the octagonal platform. It also shows the eight gallows frames mentioned in the paper. In Fig. 17, the steel shell is being erected and lowered. A view of the third step, showing the concrete caisson being driven through the sand island to solid rock, is given in Fig. 18 and, finally, Fig. 19 demonstrates the final step of removing the steel shell.

Jacob Feld,[6] Assoc. M. Am. Soc. C. E. (by letter).—The method of sinking caissons for the deep-water piers is one of the most noteworthy items in the design and construction of this bridge. Although it is not a new idea, the development of the technique and the success of the operation should result in the standardization of open-caisson construction where depths of water are not excessive.

The use of an artificial sand island for each pier eliminates the dangers from tide and current in making difficult the sinking of a caisson and also provides an easy method for the construction of the cutting-edge in true location.

The two main difficulties in caisson construction have been floating the pre-cast or lowest section (usually built on shore) and the danger from tipping during sinking. The use of a sand island eliminates both dangers. In addition, careful explorations can be made of rock contours beneath the proposed caisson and the cutting-edge can be built to suit such conditions, which practically guarantees a perfect fit when the caisson reaches rock.

Of course, when depths of water are excessive the cost of an artificial sand island may be prohibitive. In addition, the skin friction induced by the sand that has been placed artificially, increases the cost of sinking the caisson. This method might be revised in deep-water conditions by providing a steel shell enclosure driven to mud, and using such shell as the foundation for a working platform upon which the cutting-edge can be set, the lower part can be built, and the entire caisson floated therein. As a matter of record such a procedure has been used for the Grey Strait Bridge, at Brisbane, Queensland, Australia, described subsequently.

---

[6] Cons. Engr., New York, N. Y.

As far as the geology of the ground is concerned a comparison of the sub-surface investigations reported by Mr. Kirkbride, with the result of similar investigations made for the Carquinez Strait Bridge, shows almost identical conditions.[7]

The nature of the rock found at that location was the same as at the Martinez-Benicia Bridge. In addition, it was found that at the Carquinez Strait Bridge layers of sandstone and shale were often separated by beds of softer material, such as clay and in some cases gravel. It was also found that the deeper water was not above the old filled-in channel. As a matter of fact, Pier No. 4 of the Carquinez Bridge, which is above the original deep channel, is founded on piles because sound rock was not found at a depth of 200 ft. below mean high water.

Within the ten years, 1922-1932, there have been some noteworthy examples of deep caisson construction, including at least ten examples of foundation construction in which caissons were sunk more than 100 ft. below either the ground level or the water level. A short description of each of these examples should be of interest because they show the rapid development of this type of construction.

(1) In 1923, for the Rigolets Bridge, of the Louisville and Nashville Railroad Company, about 30 miles east of New Orleans, La., five steel shell caissons, 34 ft. in external diameter, with single dredging wells 16 ft. in diameter, were sunk to total depths of 80 to 113 ft. Under 45 ft. of water there was a considerable number of layers of soft black mud overlying stiff yellow clay, fine sand, and some gravel. These caissons were floated into a ring of steel sheet-piling partly driven before the caissons arrived, and the remainder of the ring was completed after the caisson had been located. The caissons were sunk entirely by open dredging methods and by the addition of concrete between the two steel rings that form them.

(2) In 1923, at Lexington, Mo., two steel cylinders, 14 ft. in diameter, were sunk to a total depth of 110 ft. Under 13 ft. of water there were various layers of sand, blue clay, gravel, and boulders. The caissons rested on soapstone. Most of the excavation was done under air, a maximum pressure of 50 lb. being used.

(3) In 1926, for the Carquinez Strait Bridge, in San Francisco Bay, caissons with a dimension of 40 by 40 ft., and 112 ft. in length, were floated into position and sunk by open dredging methods. They were built of timber with a steel covering for the cutting-edges, but with concrete posts so that, in the event the timber surface was removed the timber cross-bracing would not be exposed to the action of salt water and wood borers.

Before floating the caissons into position a guide-frame consisting of six steel spuds, 120 ft. long, was built up and anchored by four anchor barges. The conditions at the pier were 80 to 90 ft. of water overlying various layers of mud, coarse sand, gravel, and thin layers of clay, as well as shale and sandstone. The caissons were sunk to a maximum depth of 135 ft. below water level. It was noted that the friction-reducing jets placed on the exterior faces of the caissons were not of much value, whereas the cutting jets placed on the interior faces of the caissons were useful in assisting the sinking.

---

[7] "Design of Substructure of Carquinez Strait Bridge, California," by Jacob Feld, Assoc. M. Am. Soc. C. E., *Proceedings*, Brooklyn Engrs. Club, Vol. 23, April, 1925, pp. 3-34.

(4) In 1927, for the Kennebec Bridge, at Bath, Me., three of the seven caissons were sunk more than 100 ft. Two of these were 22 by 40 ft. and the third was 25 by 54 ft. The caissons were of wood, built 20 ft. high, floated, and held in position by six Chinese anchors. The excavated material was chiefly plastic blue clay and coarse sand. The caissons rest on granite rock. The excavation was done chiefly under air.

(5) In 1927, for the Umgeni River Bridge, in South Africa, six caissons, 12 ft. in diameter, were sunk to depths of 60 to 156 ft. Because of the extreme low water, sections 20 ft. in height were built in place and sunk through coarse sand and clay by open grab-bucket excavation. The caissons were built with 2-ft. walls and steel cutting-edges and sealed by tremie concrete.

(6) In 1928, for the Detroit River Suspension Bridge, between Detroit, Mich., and Windsor, Ont., Canada, two caissons, 38 ft. in diameter, were located in water varying from 8 to 25 ft. in depth. At these locations, artificial islands were built by pumping sand to above water level, and the caissons were started on top of this fill. In addition to these caissons, there were two other caissons 38 ft. in diameter and two anchorage caissons each 100 by 225 ft. These caissons were sunk by open dredging through mud and sand and then blue clay about 75 ft. in thickness, and varying layers of quicksand from 20 to 62 ft. in thickness. When the caissons reached hardpan (a layer approximately 10 ft. thick, overlying limestone rock) that material was excavated under air, and the caissons were sealed under air.

(7) In 1928, two caissons were sunk for the Mid-Hudson Bridge, at Poughkeepsie, N. Y. Each caisson was 60 by 136 ft., with a steel cutting-edge and a steel shell 20 ft. deep. A temporary wooden bottom had to be installed for floating, and the caisson was held in position by eight 15-ton anchors. The conditions were 60 ft. of water and 18 to 35 ft. of mud overlying stiff clay, sand, and gravel, the east caisson going down to Elevation − 114 and the west one to Elevation − 134. All material was excavated in the open, and considerable difficulty was encountered as has been explained in recent engineering literature.[8]

(8) In 1929, for the Federal Barge Line Terminal, on the Mississippi River, several circular caissons, 10 and 12 ft. in diameter, with 2 ft. 0-in. and 2 ft. 3-in. walls, using steel cutting-edges and steel shell forms, were sunk through 80 ft. of water and 40 ft. of sand with some blue clay. In these long and narrow caissons it was found that a balanced pressure must be maintained to prevent tipping. Sinking was performed by clam-shell excavation with the assistance of jets on the outside of the caissons.

(9) In 1929, for the Grey Strait Bridge, in Brisbane, Queensland, Australia, four caissons, 28 ft. in diameter, were sunk from 96 to 115 ft. through artificial sand-filled islands consisting of steel sheet-piling driven on a diameter of 30 ft. The first section of the caisson was built on this artificial

---

[8] *Engineering News-Record,* February 12, 1931, pp. 275–281.

sand island and was sunk by open dredging until rock was reached. The caisson was then sunk an additional 5 ft. into rock under air, using a maximum pressure of 50 lb.

(10) The latest example is that of the sixteen caissons sunk inside of 81-ft steel cylinders described in this paper, and it will be seen how the difficulties of the previous constructions have been eliminated by the methods described so ably by the author.

W. H. Kirkbride,[9] M. Am. Soc. C. E. (by letter).—The writer is indebted to those who have discussed his paper, particularly for the additional information presented.

Mr. Helmers calls attention to the use of triangulation in measurements and layout. The site of the bridge is such that direct measurements were difficult, because of the depth of water, the strong currents, and large volume of water traffic. He also mentions some of the difficulties encountered in sinking the cylinders to retain the sand of the sand islands. It must not be assumed that sinking caissons by this method is free from difficulties, but the ingenuity shown in straightening the cylinders and caissons after they had settled out of level, and in maintaining the caissons in a vertical position, resulted in landing them quite close to their true position and well within the tolerances allowed.

Mr. Clements gives additional information and points out the advantages of the use of the "sand island" method, in which the writer fully concurs. He directs attention to the fact that while the use of artificial islands is not new, the use of the rigid steel shell to enclose sand to form the artificial islands, is new. The writer recognizes this fact in his Conclusion (2), in which he referred to "artificial islands of sand within steel shells." Credit for the use of this method is due to Mr. Clements, who, as Consulting Engineer for the Contractor, was responsible for the suggestion that the method be used, and for working out the details of construction.

Mr. Schneider calls attention to the "proof-testing" of all the heat-treated eye-bars used in the bridge. When the specifications for the superstructure were under discussion, heat treatment of eye-bars was rather new and to be certain that all bars were of equal quality and conformed to the requirements, arrangements were made to "proof-test" each bar. The eye-bars before proof-testing had their pin-holes bored to a diameter sufficiently smaller than their final diameter so that after testing they could be re-bored to exact length and pin-hole diameter, thus removing any permanent set. The proof-testing consisted of applying to the bars a load of 36 000 lb per in. of nominal cross-section.

The re-boring of the pin-holes was supposed to take care of only the slight distortion that might occur. Bars with any permanent set in the body of the bar were to be rejected. It is gratifying to know that all the bars proof-tested were accepted; they were all tested to destruction and complied fully with the specifications.

[9] Chf. Engr., Northwestern Pac. R. R.; Engr., M. of W. and Structures, S. P. Co., Pacific Lines, San Francisco, Calif.

Mr. Feld gives valuable information in listing examples of deep caisson construction, and calling attention to the progressive development during the past ten years.

Mention was made in the paper of earthquake faults near the bridge and of efforts to design the superstructure and foundation to resist earthquake vibration. Since the completion of the bridge, the United States Coast and Geodetic Survey has placed a strong-motion seismograph on top of one of the piers with the expectation that the record obtained may be of assistance to engineers in developing more accurate principles as to the design of bridge piers to resist earthquakes. Similar machines have been installed in various places in California. Some difficulty has been experienced in designing a starting device that will be sensitive to slight earthquake shocks, and at the same time, not respond to other vibrations, such as may be produced by the starting and stopping of trains on the bridge, but it is believed that this trouble will soon be eliminated.

PRE-QUALIFICATION OF CONTRACTORS[1]

By C. J. Tilden,[2] M. Am. Soc. C. E.

With Discussion by Messrs. Edward W. Bush, A. B. Edwards, Samuel T. Carpenter, Leon F. Peck, C. L. Hall, A. R. Losh, E. G. Walker, and C. J. Tilden

Synopsis

A definition of pre-qualification of contractors is offered for discussion in this paper. This is supported by a brief historical comment, a statement as to legal aspects, and opposing viewpoints. Advantages and disadvantages are presented concisely, and the conclusion is reached that some form of pre-qualification is desirable from every point of view. Conditions must not be made so rigid, however, that new contracting firms would be prevented from entering the field.

Definition of Pre-Qualification

The principle of pre-qualification may be defined as "the determination of responsibility before plans and proposals are issued for bidding." This determination is based on: (1) The contractor's previous experience; (2) the kind and condition of his equipment; (3) his record on previous work of a similar character; (4) his financial condition; and (5) his character and general reputation. A more extended definition was incorporated in the California Law of 1929 (Chapter 644):

> "The Department of Public Works may, within its discretion before furnishing any persons proposing to bid on duly advertised public work, with plans and specifications for the proposed public work, require from any such person answers to questions contained in a standard form of questionnaire and financial statement, including a complete statement of the person's financial ability and experience in performing public work.
>
> "Whenever the Department of Public Works is not satisfied with the sufficiency of the answers contained in such questionnaire and financial state-

---

[2] Strathcona Prof. of Eng. Mechanics, Yale Univ., New Haven, Conn.

ment it may refuse to furnish such person with plans and specifications on any such duly advertised public work, and the bid of any person to whom plans and specifications have not been issued must be disregarded."

In a bulletin issued by the Bureau of Municipal Research, Philadelphia, Pa., in April, 1929, the following comparison was given:

"Prequalification is but an extension of the principle applied to the professions, where the possession of theory and practice must be demonstrated by the applicant and attested by diploma and State board; and in the trades, where those who would be masters must serve apprenticeships."

It is seen from the foregoing that the principle of pre-qualification is not new. It has been used to advantage for many years in private work, where the owner receives bids only from a restricted and especially invited list of contractors. The attempt to incorporate into law the principles defined herein is comparatively new, however, and has received its chief stimulus from the rapid expansion of highway building in the last few years.

History of Pre-Qualification

It has always been a generally accepted principle that municipal and other authorities had the right to withhold the bidder's sheet from a contractor to whom the award would not be made, no matter how low his bid. Similarly, public officials have always had the right to require some kind of statement of the prospective bidder's qualifications. This is usually in the form of an answer to a more or less carefully prepared questionnaire. It was incorporated into the State Laws of Wisconsin in 1925, Iowa in 1927, and California in 1929. It is required or enforced either under existing specific statute or by administrative procedure in a number of other States, and, in addition, it is used in many municipalities. Proposed legislation on the subject failed, however, in Oregon in 1929, the chief cause being a provision in the bill to the effect that if a prospective bidder takes an appeal (from disqualification), no bids shall be opened or made public until this appeal has been determined. Such a provision might evidently cause serious delay. In 1929, also, the Governor of Pennsylvania vetoed proposed pre-qualification legislation on the ground that it placed too much discretionary power in one city official, without opportunity for redress on the part of the disqualified bidder.

The recent movement in favor of pre-qualification seems to have been started about 1924 by the contractors themselves, at a meeting of the Committee of Associated General Contractors of America and the American Association of State Highway Officials. It has had the enthusiastic support of the better class of contractors ever since that time.

Legal Aspects of Pre-Qualification

Apparently, the Courts have not yet threshed out thoroughly the legal principle of pre-qualification. A city ordinance providing for pre-qualification of bidders on municipal work in Philadelphia was the basis of a suit brought by a bidder. The Court decided that the ordinance was illegal, but on appeal the judgment of the Lower Court was set aside. The case was reviewed by the Supreme Court, which declared the ordinance unconstitutional, but made several suggestions as to changes that might be made, which would keep the intent of the statute and yet be within the Constitution. One of these was the desirability of a Board of Review, composed of persons in no way connected with the department that was advertising for bids, in order to assure the bidders unbiased consideration.

This is naturally not satisfactory to city engineers. It means that they must give up a duty and responsibility that they are loathe to relinquish. Furthermore, it does not appear to be in the public interest, for engineers within the department are certainly the best fitted to handle that phase of the work. A new pre-qualification ordinance was passed by the City Council of Philadelphia and became effective September 5, 1930. This was written to include the provisions held by the Supreme Court to be essential.

The Contractor's Standpoint

From the standpoint of the general contractor, pre-qualification is decidedly advantageous. Responsible firms generally are hoping that the public will differentiate between classes of contractors, giving due weight to reliability, financial responsibility, and character, rather than making cheap price the controlling factor. Frequently, only two qualifications are required, the first being the lowest bid, and the second a satisfactory surety bond. This often militates against the responsible contractor who enters into his agreement expecting to abide by the plans and specifications and who has had experience in the technique of his work.

The surety bond is by no means complete insurance of satisfactory performance. Pre-qualification, as defined herein, will benefit both the bidder and the public. The Associated General Contractors of America has expressed itself as strongly in favor of the principle and has established a Bureau of Contract Information to co-operate with public officials and others who are investigating performance records, reputation, and general responsibility of contractors throughout the country.

Failure of Contractors

The public generally loses thousands of dollars annually in failures on contracts that have been let on the basis of the lowest bid to incompetent contractors. A large surety company has classified the causes of its losses, as follows:

	Per cent.
Inadequate financial ability	50
Incompetency	25
Dishonesty	15
Miscellaneous items, such as weather, bad luck, etc.	10

A study undertaken by the Bureau of Public Roads, United States Department of Agriculture, to determine the reason for unsatisfactory progress on Federal Aid highway projects, finds poor management the most important factor (52.7% of the cases studied), with weather (26.4%) second on the list. Inadequate financial ability, construction difficulties, and minor causes are also mentioned.

Disadvantages of Pre-Qualification

A number of objections to the principle of pre-qualification have been stated. It is claimed that competition is unduly restricted by the limitation put on the number of bidders and especially that small firms struggling to get a satisfactory hold in the industry are barred from bidding. It is claimed further that the usual requirement of a certified check is in itself sufficient evidence of competency. Objection has been made to the questionnaire that must be answered as a preliminary to putting the contractor on the preferred list, as an unwarranted intrusion into private affairs.

Public officials who are charged with the duty and responsibility of letting the work are naturally biased in favor of more competent firms of whose previous work they know. This, of course, is a serious disadvantage to the new or little known bidder. If the principle of pre-qualification is too rigidly followed, it will prevent new men from coming into the field, and as existing firms drop out, there will be no others to fill their places.

Advantages of Pre-Qualification

One of the most desirable results of pre-qualification, from the business standpoint, seems to be the increased confidence felt by manufacturers of contractors' equipment, bankers, and the surety companies. From the engineer's point of view the advantages are obvious, because he can feel much greater assurance that the plans and specifications will be followed properly. The contractors have expressed the firm belief that the principle is of benefit both to the bidder and to the public, and have supported this belief with practical co-operative efforts which tend to simplify and facilitate putting the principle into practice where it has been established.

With sworn statements at hand as to the contractor's experience, equipment, finances, and the number of contracts he has at the time, engineers can feel more confidence in the prompt and satisfactory execution of the work, and the banks and surety companies can feel greater confidence in the financial and economic phases of the question. As a protective measure to the legitimate and responsible contractor it is an important advantage.

Conclusions

There seems to be little doubt or controversy among intelligent and responsible individuals, either engineers or contractors, as to the wisdom of some form of pre-qualification. With this practical unanimity, however, there is the feeling that conditions must not be made too rigid or the statutes too exacting. Although it is highly desirable to protect the interests of the public and also those of the high-grade contractor, there should be enough leeway in the exercise of judgment of governmental officials to permit new contracting firms to enter the field.

Some form of questionnaire that will exhibit fully and clearly all the facts with regard to the bidder's financial responsibility, general character, and probable ability to complete the work satisfactorily, is highly desirable.

DISCUSSION

Edward W. Bush,[3] M. Am. Soc. C. E. (by letter).—This paper is timely and it is hoped its publication will lead to a general discussion of the subject. Pre-qualification is economic, but just now the procedure needs protection from some of its most ardent friends. Some of them are suggesting methods that are too complicated to be workable; they aim to develop certain facts of little importance; and they omit the development of other facts of prime importance on which the determination of the fitness of the contractor for the award necessarily depends. This question of the determination of the qualification of the bidder to receive the award is exactly parallel to a part of the method followed by any reputable surety company when judging the acceptability of a contract bond case; but an examination of many of the questionnaires indicates that their authors have not recognized this fact and, apparently, no attempt has been made to benefit from the very extended experience of the sureties along the same line. A surety is keenly interested in the fitness of a contractor to perform the contract properly, because if it errs in its judgment on the case it may suffer a loss. All large sureties are in touch with all kinds of construction projects in all parts of the United States and have learned by experience that human nature re-acts in about the same way on all of them. The sureties have a seasoned experience on the methods of determining the qualifications of a contractor, which if called for would assist those about to establish any scheme of pre-qualification.

When a contractor fails he is generally forced to retire from the business or continue with greatly lessened activity. Just why he failed may not be fully recognized by him, because he had never failed before, and he is apt to think that all the "breaks" were against him, etc. One never listens to a technical paper read by a contractor telling why he made a mess of his business. Active and successful contractors therefore are, perhaps, not the best qualified to outline workable pre-qualification schemes because they have not been intimately associated with trouble cases as are the sureties that pay the claims. Engineers, also, are apt to lack any extended experience in the defaults of contracts. If at any locality defaults were of frequent occurrence the premium rates would be increased greatly over the present small charge for the bond protection.

The writer is not in full accord with some points of the paper. The author defines pre-qualification as "the determination of responsibility before plans and proposals are issued for bidding." Any such procedure would necessarily cause a known list of prospective bidders to be made up well in advance of the letting, and this might prevent an outsider from breaking in on any local group that possibly might have matters fixed to its entire satisfaction. The main object is not to make an award to an unqualified bidder, but this is quite removed from a scheme of pre-qualifying all the bidders before giving out the plans. A more workable way is to state in the call for bids that no bid will be received and opened from a bidder who has not qualified himself for the contract. With such a procedure most, if not all, of the prospective bidders will qualify well in advance of the letting, but all of them will know that it is possible for some other bidder to qualify himself just before the opening, and all the benefits of open competition are thus preserved. Many contractors will not know until after they review the plans and visit the site whether or not they wish to bid, but the author's definition outlines a procedure which would tend to keep this class away from the bidding.

---

[3] Engr., Aetna Casualty & Surety Co., Hartford, Conn.

It takes time and considerable skill to verify and evaluate properly the technical and financial information submitted by any unknown contractor, and such a check should be made by the owner before making an award to any contractor not well known to be qualified. Sufficient time can be taken after the opening for such an investigation, but to make a complete investigation of all bidders before giving out the plans would be a huge task the time for which is seldom available unless the owner is willing to receive the bids from six to eight weeks after the advertisement appears. Since adequate time is, in general, not available and since, considered as a practical matter, about all the owner can expect to accomplish before the opening is to collect enough data to enable him to form a preliminary opinion that the contractor should be allowed to bid, the owner making a complete check of the bidder's affairs only if he happens to be the low bidder. This is a practical way to work pre-qualification.

If the general information on a contractor has already been filed it is available of course for subsequent lettings; therefore, only a comparatively small amount of additional up-to-date information is needed to develop a rather full understanding of the status of the bidder at future openings. It is desirable to have the pre-qualification scheme as simple as possible both in forms and procedure so as to attract instead of repel the best bidders.

The author presents parts of a California law as "a more extended definition" of pre-qualification. These excerpts show that, at its discretion, the Department of Public Works may call for questionnaires and financial statements before giving out the plans to bidders; and if the Department is not satisfied with the "sufficiency of the answers" it may refuse to furnish the bidder with the plans, etc. Apparently, the Department can neither follow up references nor verify the financial worth of a prospective bidder as it can only read the answers submitted. It is not charged with the duty of making an investigation other than along the narrow lines of the Act. No doubt the Department does not restrict its investigation to the narrow limits just stated, but the Act is not, in itself, a good definition of a workable scheme of pre-qualification. Further, it might be inferred from the wording that a contractor must have had a previous "experience in performing public work" in order to qualify, and this might bar a well qualified contractor if his experience had been gained wholly on work for a railroad company or a public utility. A better definition would be along the line of the following:

> No bid shall be received until the bidder shall have shown before the bids are opened that he has had a comparable experience in the same or similar classes of work (if a corporation, the information shall be submitted on

the experience of the personnel), also has or can obtain sufficient plant and equipment, also is possessed of sufficient financial resources as reasonably to justify the conclusion that the bidder is qualified to perform the proposed construction contract as well as continue any other contracts on hand.

In each case decisions regarding the prospective bidders shall be reached before the bids are opened, and if a prospective bidder is deemed unqualified his bid shall be returned if offered, and it shall not be received and opened.

Such a wording, if incorporated in a law or ordinance, leaves the officials a desirable freedom of action regarding the method of pre-qualification. At times an informal method could be followed. A further investigation before the award is not disbarred because all awarding bodies are now supposed to exercise discretion in the award; the new matter charges them also with the duty of investigating the bidders before the opening.

The author lists five points or elements that determine the principle of pre-qualification. He ignores other points such as the skill and ability of the contractor and the skill and experience of the contractor's organization. The surety company always collects information about these points in connection with a large contract because it wants to know that the organization will continue to function in the event that the contractor personally becomes incapacitated. Another most important element is omitted by the author as well as in the California Act, namely, information about the size, location, kind of work, and approximate percentage completed of all other contracts on hand. Are the other contracts progressing satisfactorily and profitably? A contractor has only one plant and one financial strength with which to perform all his contracts and, in the past, many new contracts have been taken by contractors with the hope that the new work will in some way supply funds needed to bolster up bad conditions already developed on other jobs. No scheme of pre-qualification is workable that neglects to give full consideration to the uncompleted work of the bidder. The sureties always investigate the other work, except in connection with small bonds written for strong contractors about whom rather full information is at hand.

The author's Point (2) indicates that the condition of the plant should be considered. It may be located here and there on other work and its condition would be impossible to determine except at a prohibitive cost. It is desirable to ask the average contractor to submit a list of the large pieces of plant, to state specifically what new plant, if any, will be needed to perform the new job if awarded to him, and to state the cost of such new equipment. The cost of new plant comes from the present working capital or net quick assets of the contractor, and, therefore, the question is always asked by a surety when underwriting a contract bond. The fact that a contractor owns plant of a certain kind is an indication that he has had experience doing the kind of work suited to the plant, and information of this kind is needed when qualifying a contractor. It is possible for a contractor to be well qualified and not own any plant, provided he knows what he should buy and has ample funds with which to purchase. The Hoover Dam was let to a new corporation having nothing but a personnel of marked ability and several million dollars in the banks.

The author presents the history of pre-qualification, its alleged advantages and disadvantages, etc., in a concise and admirable manner. The present trend among engineers and public bodies is toward a more careful selection of contractors before receiving the bids, and toward making investigations before awarding contracts. Reputable contractors favor these practices because they prevent unfair competition. The sureties, also, are in favor of the exercise of more discretion by the owners when placing contracts because no surety ever has the chance to bond an unqualified contractor until after a contract has been awarded to him. The author points out the interest the Associated General Contractors of America has exercised in helping to establish the Bureau of Contract Information, Inc.; but, apparently, in some way he missed the fact in his investigation that from its inception a select group of surety companies also has been active in the affairs of the Bureau. To date this group of sureties has contributed the major proportion of the funds used to maintain the Bureau.

The author closes his admirable paper by stating that some form of questionnaire is highly desirable, which will exhibit fully and clearly all the facts, etc., regarding a contractor. It is comparatively easy to qualify or underwrite a capable and experienced contractor as long as he keeps the scope of his operations well within the amount warranted by his working capital. When he attempts to go beyond his safe limit of volume of work more investigation of his affairs is needed and mostly this is in the line of checking carefully his alleged financial strength. The manifestly unfit are quickly disposed of, but the class between these two is the most numerous and it is also the class that causes, or should cause, the most investigation. Merely requiring answers to certain questions will not in itself establish for this class the fitness or disqualification of the bidder to receive an award, although the answers will probably direct the course of the inquiry. Some of the questionnaire forms are good, but more of them are very poor working tools for an engineer or a public works body. Any of them could be improved and as this important subject is still in a state of flux, it would seem desirable that an organized study should be made to develop the best thought regarding it. Recently, many bills on pre-qualification have been offered to State legislatures. Some of these bills have proposed non-workable schemes advocated by zealous but poorly informed individuals or societies. Many persons desire the benefits of pre-qualification, but do not know a good workable way to obtain them.

A. B. Edwards,[4] M. Am. Soc. C. E. (by letter).—To accept a bid without a demonstration of the aptitude, ability, integrity, and experience of the bidder would be economically foolish. In contrast with this clumsy procedure is the policy of determining the qualifications entering into the make-up of the bidder who can and will co-operate with the engineer to give the owner his money's worth.

The bidder should be able to assume full responsibility for the planning and execution of the work of construction in accordance with the commercial requirements of the owner, as outlined by the engineer. The bidder in whom confidence and responsibility is thus placed, will be developed by pre-qualification.

---

[4] Asst. Engr., Div. of Met. Planning, Commonwealth of Massachusetts, Boston, Mass.

One potent aid in the establishment of pre-qualification as a permanent policy may be the equitable handling of candidates for membership in the fraternity of bidders. There are those who have served their apprenticeship without submitting to the enervating influences of expediency, who are adequately trained in sound procedure, and who are worthy of financial backing. Pre-qualification can and should give these canditates "elbow room" by combating the unworthy element.

Samuel T. Carpenter,[5] Jun. Am. Soc. C. E. (by letter).—That some form of pre-qualification or qualification is necessary to determine the responsibility and financial standing of contractors is undeniable. To what extent it can be developed in order to place no restriction on competitive bidding is problematical. For the public's interest the presentation of a surety bond should not be taken as conclusive evidence that the finished product will be satisfactory. Specifications for public work usually carry a clause demanding the contractor to guarantee his work fully from defects for at least a year after completion. In the writer's opinion too much dependence is placed upon this clause to insure a satisfactory product. The engineer deserves a finished product that will be a tribute to his engineering skill, and the legitimate contractor deserves a protection against those who are obviously unable to complete a building program successfully, either financially or technically.

Professor Tilden states five basic criteria for determining the fitness of a contractor to receive plans and proposals for bidding. In addition, it might be well to investigate his organization, personnel, and their experience.

In 1929 the State of Indiana adopted a form of qualification that provides for a questionnaire to be submitted by the contractor with his proposal. Section 1 of the Indiana statute[6] that covers this form of qualification stipulates that when any public work aggregating $5 000, or more, is to be constructed or repaired under contract, it must be let to the best of the lowest bidders. Section 2 provides means of classifying the bidders. Each bidder must submit a sworn statement of his experience, his proposed plan, and the equipment he has available for doing the work. Standard forms for this purpose (General Form 96-*a*) are supplied by the State Board of Accounts, which are designated the experience questionnaire, plan and equipment questionnaire, and the contractor's financial statement.

Leon F. Peck,[7] M. Am. Soc. C. E. (by letter).—The writer fully realizes that a brief should be submitted whereby some lowest bidders should not be awarded the contract. Evidently, this discrimination has been practiced unfairly for many years. It is not new, but those interested are trying to set up a method of making the award with fairness.

[7] Supt., Dept. of Streets, Hartford, Conn.

The fact that engineers are discussing means of doing this would indicate that there might be some question as to whether it can be done fairly both to the contractor and to the public, where public funds are involved.

This is a big step, seemingly in the opposite direction from that recommended in 1912 by Maj. Cassius E. Gillette, then President of the American Society of Engineering Contractors which had an active existence over a period of a few years before the World War interruption.

Major Gillete stated in a prepared paper,[8] that he had made investigations of three sets of public contracts and found a loss of $8 600 000 out of a total of $18 000 000 worth of contracts. He said it was partly due to the clause in specifications granting discretion to the awarding officials. He also stated that in all these cases, covering dozens of contracts, the invariable accompaniment of the cheat was the scarcity or absence of real competition, and that under the shelter of that potent word, "discretion," fraudulent and unwise public contracts had been let and interpreted so as to cause the loss to taxpayers of the United States of untold millions, and to rob hundreds of bidders of their just rights.

Major Gillette believed that the American Society of Engineering Contractors should sponsor a bill in every State Legislature in the United States, making it compulsory that no request for bids on public work should be advertised until the appropriation was available, and that the contract must be awarded to the lowest bidder. He had had such wide experience and had given this subject such prolonged study, that it would be unfair not to give his views cognizance at this time.

C. L. HALL,[9] M. AM. SOC. C. E. (by letter).—This interesting, but all too brief, discussion of the merits and demerits of pre-qualification avoids the question of the political factors involved. The construction of public works, like any other act of the State, is necessarily political in origin and in final control. It is imperative, therefore, that the political effect of any phase of public construction be considered. The writer desires to point out that political history may throw some light on the letting of contracts.

All discussion of pre-qualification is based on the theory that, in general, the owner who is to use the work to be built can best protect his own interests by restricting competition to contractors whom he knows are capable of doing the work. In engineering matters, the wise owner follows the advice of an engineer whom he has selected. Usually, the elimination, through error, of a qualified contractor will cost the owner only the comparatively small sum of money representing the difference between the successful bid and the bid which the eliminated contractor would have submitted. On the other hand, even with excellent inspection, an unqualified contractor can sometimes cause an owner very large losses. In almost every case the relatively slight sums he can save the owner by his lower bid at least are balanced by the diminished value of any structure upon which the construction work has been below par, or by the increased cost thereof, if the inspection cost has been unduly high.

---

[8] "Competition in Public Contracts", *Journal*, Am. Soc. of Eng. Contractors, Vol. 4, Pt. 1 (1912), p. 87.

[9] Lt.-Col., Corps of Engrs., U. S. A., U. S. Engr. Office, Cincinnati, Ohio.

If the odds are thus weighed, and the owner is assumed to be capable of exercising an intelligent care of his own money, an iron-clad case can be made out for pre-qualification.

In works of any magnitude, however, the owner is usually an abstraction, such as a corporation. In public works, the owner is so much of an abstraction, that he cannot really be identified at all. In order to visualize him those who have dealings with any particular branch of the owner government as to any work, usually refer to the bureau or State commission in charge as the owner. These organs do not resemble very closely the wise private owner.

During the scandals of reconstruction, a half century ago, the contracting officer did not usually yield to crude bribery, but he frequently exercised his official discretion for the benefit of the political organization which, rather than the abstract public, was responsible for his appointment. He thus tended to award contracts for the benefit of contractors, who presumably rewarded the political organization with a share of the profits. It was the scandals that followed this relationship which caused the passage of the strict laws relative to open bidding on public works, now generally in force both in the Union and in the States.

Federal specifications, and most State specifications, even in States that have been most conservative in modifying the general laws, give a contracting officer the right to reject the bid of a contractor who lacks the requisite plant or experience. Rejection after bids are opened, or post-qualification, however, involves many inconveniences to the contracting officer. He may be accused of favoritism, or even of corruption. If the protesting bidder has, or can arouse, political or press influence in his behalf, the officer may be reversed by his political superiors. It is simpler to prevent such difficulties by pre-qualification.

With the present improved standards of honesty among public officials, there is no doubt that pre-qualification does little harm at this time; but it is only human nature for contractors to form a trade association in their own behalf. They have, assuredly, many data to support claims that inexperienced contractors injure the public. Once such an association is formed, it will also be human nature for it to grant new admissions reluctantly. If the association allies itself with employee bodies containing a large number of voters, and if the contractors play politics, the closed contractor list may become a reality.

Professor Tilden's conclusions point out some of the dangers of the closed list, even on the assumption that contracting officers act with complete independence, and in perfect good faith; but complete independence is rarely possessed by non-political officers; nor is good faith always a quality of political appointees. Moreover, the permanent officer, who is most likely to possess both these desirable characters, is by nature a conservative. He prefers to deal with contractors whom he knows. Everything thus conspires to keep a closed list closed.

Humanly speaking, it is certain that a closed contractor list will cause a repetition of the very evils that strict public works laws were designed to suppress. It is at least probable that pre-qualification will produce such a list. Post-qualification in the light of day, as is the present practice of the Federal Government, does not cause these evils. This system is possible if the State has a permanent engineering force, with an *esprit de corps* of its own, and if local public opinion refuses its support when the engineer is over-ruled by the politician on technical matters. These may be counsels of perfection; on the other hand, without such a public organization, it will be impossible to prevent scandals following pre-qualification. The writer, therefore, concludes that statutory pre-qualification would cause disadvantages outweighing its undeniable advantages.

A. R. LOSH,[10] ASSOC. M. AM. SOC. C. E. (by letter).—This is a timely subject and one worthy of careful consideration. The large volume of public works contracts now under way (1932) and the dependence of the construction industry upon such contracts, make it necessary that the best business principles shall prevail. An efficient, qualified, responsible contractor is just as essential as an engineering organization with the same qualifications. Professor Tilden has presented the general features of pre-qualification in an excellent paper, and the writer would like to add a few brief comments, particularly with reference to the advantages of pre-qualification.

There appear to be a number of advantages not brought out in sufficient detail by the author. The administrative authorities on public works are relieved of the responsibility and inconvenience of assisting in collecting unpaid bills from contractors. They are relieved from the criticisms which always follow in the trail of a bankrupt contractor, of merchants, material men, laborers, and others who may sell their goods or services to the contractor. Many people who are not informed as to the provisions of public contracts and surety bonds, will sell contractors or their employees almost anything, feeling that the State or other public authority will protect them. They also feel that an organization that is qualified to receive a contract on public work must have a first-class credit rating.

Surety bonds usually protect the State in securing work within the specifications and time limits, but they do not fully protect the public from losses due to the failure of the contractor to pay his bills. Laborers and small businesses cannot afford to employ attorneys and go into Court to collect their accounts. There are occasions without number where contractors, and subcontractors, or employees, buy goods or obtain services that are not directly related to public contracts, but the uninformed public is not aware of these conditions and is without protection.

Surety companies occasionally fail, and the public is left without protection. The public official cannot specify the surety, but must accept any that is offered as long as it has a satisfactory rating. All surety companies do not handle contractors' claims on the same basis.

Companies that sell materials and equipment will be assured of receiving payments for their goods and will compete for business, resulting in a lower cost to the public. Contractors in good financial standing, who are in position to discount their bills, frequently buy cheaper than the State, while those contractors whose credit is in doubt, must pay a higher price.

---

[10] Mgr., Asphalt and Road Oil Div., Anderson-Prichard Corp., Oklahoma City, Okla.

Pre-qualification will have a stabilizing affect on the construction industry which, in turn, will permit the development of better organizations, more efficient work, and, in the end, reasonable prices. Certainly, on public work, prices should not be unreasonably high, or low. Fair prices for materials, living wages, a reasonable profit for the contractor, and the work done as required by the plans and specifications, are the desirable ends to be obtained in the termination of a public works contract.

On the side of disadvantages of pre-qualification, the need is only to guard against restricted competition. To offset this there is always left open to the administrative authority the threat to do the work with its own organization if the bids exceed the engineer's estimate.

E. G. Walker,[11] M. Am. Soc. C. E. (by letter).—The wisdom of adopting some form of pre-qualification is apparent. Stripped of its special signification, the author's statement to this effect merely expresses a fundamental principle of commercial dealing which recognizes that price is only one of the guiding considerations in entering into a business transaction. Unfortunately, the plain common sense of a private deal has a tendency, when applied to the control of public undertakings, to become involved in an elaboration of laws, rules, and red tape. While these are devised primarily for the avoidance of the possible temptation of unethical practice, they also have the tendency to replace the responsible exercises of judgment by the mechanical application of rules. There cannot be any doubt of the practical necessity of a preliminary assessment, by the engineer responsible for the project, of the suitability of the proposed contractor, but there is grave doubt as to the propriety of working strictly by rule in making such assessment. There are many qualifications and attributes of a contractor which may make or mar the execution of a contract, and which are not susceptible of expression in a questionnaire. It is not desirable, therefore, to deal with this matter by formal rules of procedure.

It is the essence of public control that there must be public knowledge of the intention to let contracts for public works and services, and that the terms of these contracts must be fulfilled in the manner that is most economical to the community. The public interest, however, is not served by awarding contracts to the lowest bidder irrespective of other considerations. Hence, there must be some form of limitation in order that the responsible authority may fulfill its function of obtaining the best results for the public it represents. It should be advised, therefore, by a competent engineer who should be free to investigate the claims of competing contractors, and to make recommendations supported by reasoned arguments. In considering his report, the engineer should be free to make such inquiries as appear germane to the issue, and to form his opinions without the limitations of a schedule. In spite of the development of the large contracting company with its complex and sub-divided organization, the successful execution of a public works contract is, to-day, as much dependent upon the individualities of the men in control, as it was in the days of the private individual who made a personal contract for executing works. This must be taken into account adequately in comparing the proposals of competing contractors.

---

[11] (Maxted & Knott), London, England.

The prime duty of the engineer is to endeavor so to serve his client as to obtain the best possible results for him within the limitations of the proposition. In order to do this effectively, the engineer has frequently to settle details which involve the striking of a fair balance between the claims of the client and those of the contractor. To do so successfully an evenness of judgment must be developed, which, if properly applied in the initial stages of the making of the contract, will go a long way to facilitate the execution of the work for all concerned therewith. After some years of experience of both public and private works, the writer submits the following three suggestions:

1.—Where the nature of the work and of the interests for whom the work is to be executed, makes public advertisement of the proposed contract essential, it should be open to all contractors to tender; but essential safeguards should be inserted to make clear that the work will not necessarily be awarded to the lowest or to any bidder and, by the requirement of suitable deposits and securities by contractors, precaution should be taken to insure that only proper and serious bids are made.

2.—In cases where public announcement of the proposal is not necessary, it should be within the power of the engineer to invite an agreed number of selected contractors to bid, the engineer having first satisfied the authority responsible for the work as to his reasons for selecting the particular contractors.

3.—In any case, after bids have been received, it should be the duty of the engineer to make such inquiries in any direction as he should think fit, in order to assure himself of the suitability of the contractor before recommending the acceptance of his bid. Naturally, such an investigation would have to be comprehensive or simple, according to the knowledge available from previous transactions. It is essentially a matter in which the procedure in each individual case must be evolved at the time, and cannot be met by the filling in of a pre-arranged form.

It does not seem that the adjudication on the suitability of a contractor to undertake work for which he may compete, can be controlled in detail satisfactorily by legislation, with all the rigidity and limitations which must inevitably accompany it. The subject should be treated in a far more elastic manner. The most suitable treatment is obtained by the employment of competent and honest engineers, and by leaving them full responsibility as outlined herein, subject to the control of the responsible authority. The code of ethics of the Society is a sufficient safeguard to any community served by competent qualified engineers.

C. J. TILDEN,[12] M. AM. SOC. C. E. (by letter).—In closing the discussion of this paper the writer wishes first to review briefly the way in which it came to be written. The Highway Division of the Society chose the subject as the topic for discussion at its meetings in 1930. Two meetings were held, one in April and one in October, at which papers were presented and discussed. Fifteen gentlemen stated their views either in writing or orally. The writer was asked to summarize this material and get it in shape for publication. A paper was published in *Civil Engineering*, for March, 1931, in which the real authors of the views expressed were named.[13] Once again the task was imposed of further condensing the article for publication in *Proceedings*. The present paper was the result. Even a foster parent has an affection for his child, and it is a source of great pleasure to the writer that so many have taken the trouble to discuss it.

---

[12] Strathcona Prof. of Eng. Mechanics, Yale Univ., New Haven, Conn.

Mr. Bush, who brings to the discussion the combined wisdom of an engineer and an official of a surety company, makes the interesting suggestion "to state in the call for bids that no bid will be received and opened from a bidder who has not qualified himself for the contract." This would mean a special pre-qualified list prepared in advance for each contract. He urges the desirability of having any scheme of qualification as simple and direct as possible so that good bidders will not be frightened off. He speaks further of the advantage of including in the list of basic elements determining the principles of pre-qualification some measure of the skill and ability of the contractor and the skill and experience of his organization, together with the information about other contracts which he may have in hand. These might be assumed to be included under the general heading of "previous experience" and "character and general reputation," but they are important enough to be mentioned specifically by themselves. Mr. Carpenter also stresses this point.

Mr. Peck quotes the stand taken by Maj. Cassius E. Gillette about twenty years ago, at a time when he was President of the American Society of Engineering Contractors, an organization which appears to be no longer in existence. The views which Major Gillette held in 1912, as a result of careful consideration of the whole question, are nevertheless interesting reading and worthy of note.

Colonel Hall has presented a singularly clear and able brief for the opposition; that is, emphatically against the principle of pre-qualification. In all, about twenty-two individuals have given their views, including those who presented the first group of papers and discussions. Of these, fourteen express themselves in favor of the general principle of pre-qualification; six are noncommittal or deal in their discussion with other phases of the question; while only two are opposed. One of these is Mr. Peck, who quotes Major Gillette as being (in 1912) opposed to the principle; the other is Colonel Hall. Colonel Hall, then, is the emphatic representative of the case against pre-qualification. His discussion is so clear and excellent in every way that it should be read by all who are in any way concerned with the application of the principle. His conclusion, as stated in the last sentence of his discussion, is that "statutory pre-qualification would cause disadvantages outweighing its undeniable advantages."

---

[13] "A Summary of the Present State of Prequalification," *Civil Engineering*, March, 1931, p. 504.

On the other hand Mr. Losh thinks, that the advantages of pre-qualification are not brought out in sufficient detail in the original paper, and he proceeds to cite some of these advantages. He calls attention especially to the necessity of guarding against restricted competition.

Mr. Walker, writing from London, England, is mildly in favor of pre-qualification, but thinks it should be applied with modifications which he sets forth under three heads.

In general summary then, there seems to be a decided majority in favor of the basic principle of some form of pre-qualification of prospective bidders on public work. Just what form it should take appears to be subject to a rather wide range of opinion. Whether a generally satisfactory statement looking toward statutory principles could be written at this time is a matter of doubt.

TESTS FOR HYDRAULIC-FILL DAMS[1]

By Harry H. Hatch,[2] M. Am. Soc. C. E.

With Discussion by Messrs. Charles H. Paul, Joel D. Justin, Jephtha A. Wade, Stanley M. Dore, D. P. Krynine, M. M. O'Shaughnessy, Joel B. Cox, William P. Creager, and Harry H. Hatch

Synopsis

This paper describes some of the tests made for the City of Springfield, Mass., on the Cobble Mountain Hydraulic-Fill Dam. The derivation is given of almost all the formulas used in the paper. In addition to new formulas and data pertaining to tests, the paper contains a consolidation study of core materials and a seepage formula for hydraulic-fill dams. It also gives the results of the gradation tests made at Cobble Mountain Laboratory of the core materials of several other hydraulic-fill dams.

Its main object, however, is to arouse interest among engineers connected with hydraulic-fill construction, with a view of standardizing methods of testing materials in hydraulic-fill dams. Opinions differ; engineers on each job devise a different method of testing; and it is time that a definite step is taken and a standard method developed in making tests for this particular kind of construction.

The original manuscript, which is several times the length of this paper, is on file for reference in Engineering Societies Library, 33 West 39th Street, New York, N. Y. It contains forty-one illustrations, including curves of many of the equations.

Purpose of the Laboratory

Hydraulic-fill dams are almost new compared with other types, and they are becoming more popular because of their many advantages. Unfortunately, methods of testing materials for such dams have not been standardized. No doubt the materials for different dams at different locations are not the same, and many dams have local problems; but in the main a standard method could be devised, such as is being used for cement and other materials of construction, and, whenever necessary, this method could be modified for local conditions. After all, the requirements of the core and beaches of a hydraulic-fill dam are the same for any dam and at almost any location.

---

[1] Presented at the Joint Meeting of the Irrigation and Power Divisions, Yellowstone National Park, Wyoming, July 7, 1932.

[2] Engr. in Chg., Cobble Mountain Reservoir, Springfield Water-Works, Blandford, Mass.

Heretofore, the methods of testing the borrow and core materials of hydraulic-fill dams have not been along the same lines. As a rule, the ordinary sieve analyses have been made with the statement that a certain percentage of the material is finer than a 100-mesh or 200-mesh sieve. Often the sieves are not even rated; for sieves finer than the 200 mesh the methods differ greatly, and as could be expected, the results are not always entirely reliable. The purpose of Cobble Mountain Laboratory was to make all the tests necessary for this kind of construction and also to establish a satisfactory, and yet practical, method of grading the material finer than the 200-mesh sieve to at least 0.01 mm.

The fact that the laboratory was established on the job proved of great advantage in keeping a close control of the borrow and sluiced materials of the dam.

SAMPLING

In making the preliminary studies on borrow-pits for the determination of the percentage of a critical size and also for making the gradation curve of the borrow material, one must have a representative sample of the pit. Since the gradation curve must show the material that will go over to the dam, it should not include the large boulders in the pit that will be left behind.

FIG. 1.—CROSS-SECTION OF PROJECTILE SAMPLER.

Particular care and special equipment are required to secure representative samples from the core of a dam during its construction. At Cobble Mountain the so-called projectile sampler, designed by the Staff of Murray and Flood, Engineers, shown in Fig. 1, was used. Essentially, it consists of: (1) A detachable container for the sample (about 400 cu. cm.); (2) a casing containing the plunger-valve spring, with three openings for admittance of the sample material; (3) a valve and spring operated by pull on the sash cord; (4) a standard, ¾-in. pipe; and (5), the sash cord extending to the surface of the core pool. The sample, taken out with the projectile sampler from a more or less consolidated core, will be of no value for the determination of moisture content or percentage of voids. It is almost impossible to bring out the sample in its original condition with this device.

The following method was found to be satisfactory for taking out samples in their original condition from a consolidated core. One 2-in., or one 1½-in. pipe (or a series of them coupled to any length), having the bottom covered with a canvas, was lowered to a desired depth by means of additional weights. After making sure that there was no water at the bottom of the pipe, a ¾-in. pipe was lowered inside the larger one. The smaller pipe had a piece about 1 ft. long at the bottom, which was beveled to a cutting-edge. The smaller pipe was forced down (the cutting-edge piercing the canvas) into the core about 1 ft., or more. Then it was raised, and its lower end section was uncoupled. The sample was forced out by a wooden piston, and was immediately brought to the laboratory where the moisture content and percentage of voids were determined as soon as possible.

Specific Gravity

The specific gravity of the materials is of great importance. After the value of the specific gravity is determined definitely, it should be checked occasionally to see whether there is any variation. The tests at Cobble Mountain Dam were made essentially as described[3] in the method for testing cement of the American Society for Testing Materials.

The Percentage of Voids

The percentage of voids and moisture content are related, and they give a good idea of the consolidation of the core. The late Allen Hazen, M. Am. Soc. C. E., stated[4] that,

> "The percentage of voids furnishes, on the whole, the best index of consolidation and stability. In itself, it is not an adequate basis of comparison, because different kinds of core material may have different degrees of stiffness with the same percentage of voids; but, notwithstanding this difference, the percentage of voids is the best index of consolidation so far available."

The determination of the percentage of voids, if it is done accurately, is essential. It is readily seen that the unit weight (and, therefore, the acting and resisting forces) and the coefficient of permeability of the different parts of a dam are directly dependent on, and the coefficient of friction is affected by, the percentage of voids of its material.

If at any depth and location in the core a sample in its original position with its original moisture content can be brought to the surface, the moisture content of the core in the dam at that particular elevation can easily be computed. In saturated core material all voids are filled with water and, when the specific gravity of the material is known, the percentage of voids can be computed by the formula,

---

[3] Specifications C9–26, Am. Soc. for Testing Materials.

[4] "Hydraulic-Fill Dams", by Allen Hazen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 1718.

$$V = \frac{w}{w + \dfrac{(100 - w)}{s}} = \frac{100\ ws}{ws + (100 - w)} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which, V equals percentage of voids; w, percentage of water by weight; and, s, specific gravity of core material. The computation is simple and can be made readily, or the equation can be interpreted into a set of curves from which values can be picked.

Two methods were used in the determination of the percentage of voids in the beach materials—the one for the beach material near the core limits, where the particle sizes are small, and the other for the beach material near the toes, where the particle sizes are large.

For beach materials with particle diameters up to about ¼-in., brass cylinders, 4 in. in diameter and 6 in. long, were used. One end of the cylinder was beveled to a cutting-edge to facilitate forcing it into the beach. Each cylinder was pressed into the beach and then removed with a shovel having considerable material above and below it. The top and bottom of the sample were neatly cut with wire, giving a sample equal in volume to that of the cylinder. The material was then dried and weighed, and the percentage of voids computed.

For larger particles near the toes of the beach, a steel pipe, 20 in. in diameter and about 3 ft. long, open at both ends, was used. At places where the samples were taken the surface material was scraped down to a level and undisturbed section in the beach. The pipe was forced down by sledge hammer only 4 or 5 in. at a time; then the inside material was cleaned out and set apart. Later, it was forced down a similar distance, and the operation continued until about 4 cu. ft. of sample material was obtained. After it came out of the pipe, the test material was weighed in the field and a sample was brought to the laboratory for moisture-content determination. With this information the dry weight of the sample in the field was computed and the percentage of voids determined.

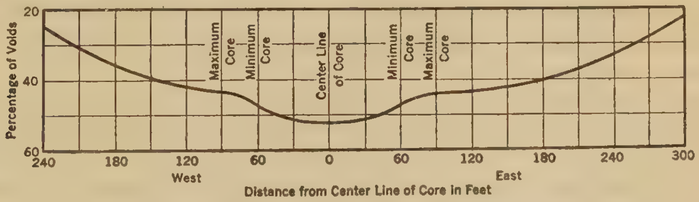

FIG. 2.—PERCENTAGE OF VOIDS ON A SECTION OF COBBLE MOUNTAIN DAM AT DIFFERENT DISTANCES FROM THE CENTER LINE OF THE CORE.

It was noted that the percentage of voids was at its maximum in the core pool, decreasing toward the toes (Fig. 2). The reason for this may be due to the fact that the beach material is deposited by running water and that the core material held in suspension is deposited by settling in comparatively still water. Furthermore, the material close to the core limits is more or less uniform in size, whereas farther away from the core section the beach material becomes larger, has a better gradation, and, therefore, a smaller percentage of voids.

The percentages of voids shown on Fig. 2 are not final and are good only as a comparison in showing the variation in consolidation of the various points in the dam at or about the same elevation. Undoubtedly, due to increased weight above, the consolidation shown in Fig. 2 will be somewhat increased as the dam is completed and as the final settlement takes place.

PENETRATION TESTS

A method previously used has been to make the penetration tests in the field by two strong men forcing down one 1½-in. pipe into the core as far as it will go. It has been stated that when the pipe is forced down, the core material at the elevation of the bottom of the pipe has 50% voids. The definition of "two strong men" is rather uncertain, and it is doubtful whether 50% voids could be obtained for any two materials at the elevation of the bottom of the pipe, even if the force exerted by "two strong men" was constant and known. Experience shows that the penetration of the pipe is affected not only by the percentage of the voids in the core, but also by the grain sizes and other physical characteristics of the core material.

To obviate any uncertainty in regard to the force necessary to reach the penetration limit on the 1½-in. pipe, definite loads up to 600 lb. were applied to sink it. A complete operation was conducted for each loading. In some cases, the bottom of the pipe was tied with greased canvas to prevent mud and water from getting into it. However, it was found that the depth of penetration was not materially affected by the canvas at the bottom of the pipe. When the penetration limit was reached for any loading, the weights were removed, and samples were taken from the core by the ¾-in. pipe, as described under "Sampling," at the elevation of the bottom of the 1½-in. pipe, and the percentage of voids of the material was computed.

It was discovered that by applying the total load at the beginning of the test, the pipe would penetrate farther into the core than by applying the same total load in fractions at different intervals during the process of penetration, when it took time to make the necessary additional connections and to increase the loading. In every instance, the latter case gave about 2 or 3 ft. less penetration.

It is evident that there is a distinct relation for the same material between the total load applied to the 1½-in. pipe and the percentage of voids of the core material at the elevation of the bottom of the pipe. Once this relation is established for any one material, it will not always be necessary to determine the percentage of voids for every test.

Notwithstanding the personal equation both in the field and in the laboratory, the difference in physical characteristics, and the difference in the grain sizes of the core material, the numerous tests gave the following approximate relation between the percentage of voids of the material and the total load causing the penetration:

$$100 - V = 33\,L^{0.067} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which, V is the percentage of voids, and L, the load, in pounds, including the weight of the $1\frac{1}{2}$-in. pipe. As in the case of Equation (1) this formula can easily be expressed in curve form for easy reference. In winter, it was more convenient to carry on this investigation by building a timber tower over the ice on the core pool, in order to facilitate the operations necessary for conducting the test.

RATING SIEVES

The mesh openings of a sieve given by the manufacturer, or their exact measurement, will not give the actual separation sizes of the material. Certain rules have been established to apply to the nominal mesh openings of a sieve in order to obtain its actual separation; but it is desirable to determine the actual separation of the sieves used on the job for the particular material on hand. The shape and other characteristics of a material will affect the value of the separation. A sieve will not necessarily have the same separation size for different materials. In fact, rating of the same set of sieves should be repeated from time to time as the meshes will wear and some of the finer meshes will get clogged.

The 200-mesh sieve is the most unreliable in this respect; it requires constant watching. The rating of sieves on the Cobble Mountain Dam was conducted along the principles outlined[5] by the American Water Works Association. The variation in separation sizes is shown in Table 1. The No. 3 rating was checked by microscopic examination, and its variation was found to be due to differences in the shapes of particles.

TABLE 1.—THE VARIATION IN SEPARATION SIZES OF THE TYLER SIEVES USED AT COBBLE MOUNTAIN

ELUTRIATION

A sieve analysis with a minimum mesh of 200 is limited to about 0.09 mm. in diameter, whereas it was necessary to carry an analysis to at least 0.01 mm., or about one-tenth the particle sizes of the 200-mesh limit.

Elutriation by the decantation method, as described[6] by F. E. Turneaure and H. L. Russell, Members, Am. Soc. C. E., has been used to analyze sand that passes a 200-mesh sieve. The tests at Cobble Mountain Dam were made to control the sizes of the core material during construction. The method cannot be practical because of the lack of automatic control in operations and because of the many personal equations entering into the test, not to mention the slow process. Hence, it became necessary to develop a practical method that would take a reasonably short time to make tests of a few samples a day with reliable results, and, therefore, a practical apparatus for elutriation was designed, and grading by elutriation was adopted.

---

[6] "Public Water Supplies", by F. E. Turneaure and H. L. Russell, 1910, p. 472.

Various types of elutriators[7] have been used in laboratories for some time, some of them dating back to about 1900. For the first time, at Cobble Mountain Dam, an elutriation method was used in a practical way for the control of the core material of a dam under construction.

FIG. 3.—ONE UNIT OF ELUTRIATOR TO SHOW OPERATION.

The apparatus (see Fig. 3) consists of three glass cones of different sizes, each provided with an inlet tube running to the bottom and an outlet tube running to the next cone. The first cone inlet tube has a connection to a glass funnel into which the test material is first placed. From this funnel, the material is carried to the first, then the second, and then the third, cone which has a connection to a glass nozzle that discharges the overflow into a large glass jar.

---

[7] "Clays", by Heinrich Ries, 1927, pp. 198–202.

With the arrangement of the inlet tubes, a rising column of water is created in every cone, each with a different velocity, due to the different cross-sections of the cones. When the sample is washed through the glass funnel into the first cone only the larger particles settle because at this point the water has its greatest velocity. The smaller particles are carried over into the next cone. Similarly, the same action takes place in the other cones, the particles settled in them having a definite relation to their areas. The test is continued until the overflow discharge becomes almost clear. At the end of the run the particles at the bottom of each cone are recovered by a process of filtration through alundum crucibles under a vacuum, and the overflow is flocculated with chemicals and then filtered.

The Cobble Mountain elutriator has four units, so that four tests can be run at the same time. All the units are submerged in water in a steel tank. The flow of the water through the cones is kept constant by a weir box, in which the head is constant, attached to the tank. The thermostatic control and the circulating pump keep the water at a constant and uniform temperature throughout the tank and in the cones. With a correspondingly longer tank, almost any number of elutriator units can be installed and as many tests run at the same time.

THE ELUTRIATOR FORMULA

The elutriator formula is derived from Stokes' law[8]:

$$v = \frac{2}{9}\,\frac{(P_p - P_l)}{n}\,g\,r^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which, v is the velocity of fall, in centimeters per second, P_p, density of particle; P_l, density of liquid; g, gravity constant, in centimeter-gramme-seconds $= 981$; r, radius of particle, in centimeters; and n, coefficient of viscosity, in poises.

For working purposes, the flow through the elutriator tubes should be expressed in cubic centimeters per minute and the diameter of the particle in millimeters. Then, $60\,v = 60 \times \frac{2}{9}\,\frac{(P_p - P_l)}{n}\,981\left(\frac{d}{2 \times 10}\right)^2$; but, $60\,v = \frac{\text{cubic centimeters per minute}}{\text{square centimeters}}$; therefore,

$$\frac{\text{Cubic centimeters per minute}}{\text{Square centimeters}} = \frac{60 \times 2 \times 981}{9 \times 4 \times 100}\left(\frac{P_p - P_l}{n}\right)d^2$$

$$= 32.7\left(\frac{P_p - P_l}{n}\right)d^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Without appreciable error values of specific gravity instead of those of density can be substituted for P_p and P_l. Let $P_p = 2.72$ for Cobble Mountain material, and $P_l = 1.00$. Then, $P_p - P_l = 1.72$. Substituting this value in

---

[8] Mathematical and Physical Papers, by G. G. Stokes, Vol. III, p. 60, Cambridge Univ. Press, 1905.

Equation (4) and solving for d,

$$d = 0.13334 \sqrt{\frac{\text{cubic centimeters per minute}}{\text{square centimeters}}} \sqrt{n} \quad \ldots\ldots\ldots\ldots (5)$$

which is the elutriator formula. By inserting the actual values of the flow, area of the tube, and the coefficient of viscosity, in Equation (5), the diameter of separation can be computed in millimeters.

Instead of the viscosity coefficient, it is proposed to use the temperature factor, $\frac{60}{t+10}$, in degrees Fahrenheit. The relation between the coefficient of viscosity and $\frac{60}{t+10}$ is not strictly constant (see Fig. 5); the relation factor varies from 0.01274 to 0.01311 for a range of temperature from 40° to 90° Fahr. The average value of 0.01296 was adopted to apply to the range of working temperature for this factor; thus,

$$n = 0.01296 \left(\frac{60}{t+10}\right) \quad \ldots\ldots\ldots\ldots (6)$$

Substituting for n in Equation (5) the value from Equation (6) and making the necessary reduction,

$$d = 0.0152 \sqrt{\frac{\text{cubic centimeters per minute}}{\text{square centimeters}}} \sqrt{\frac{60}{t+10}} \quad \ldots\ldots\ldots\ldots (7)$$

Equation (7) is the one used at Cobble Mountain Reservoir. Eleven microscopic measurements were made at the hydraulic-fill laboratory, and their values for the constant, 0.0152, in Equation (7) were: 0.0155, 0.0154, 0.0172, 0.0163, 0.0157, 0.0155, 0.0157, 0.0151, 0.0165, 0.0151, and 0.0161. The average of these eleven values is 0.0158 compared with 0.0152 as computed. The difference, which is probably due to shape of particles, is negligible, and the two results agree satisfactorily.

Stokes' law gives the constant velocity of falling bodies with a certain diameter through a liquid, whereas, in this case, the same law applies to bodies of the same diameter held in suspension by, or resisting the upward flow of, the same liquid, having, of course, the relative values given in Equation (7).

In order to obtain reliable results for a test, it is necessary that the flow (in cubic centimeters per minute), and the temperature (t° Fahr.) factors of Equation (7) should remain constant during the run of the test. The weir box furnishes a constant head, and a desired uniform flow can be had throughout the run from a small quantity to about 80 cu. cm. per min. The heat control can be set to a desired temperature, and it will work automatically to keep the water at that constant temperature. The circulating pump, of course, will insure a uniform temperature for the water throughout.

The net cross-sectional areas of the cones are: $A_1 = 4.65$; $A_2 = 20.81$; and $A_3 = 85.00$ sq. cm. With a flow of 48 cu. cm. per min. and $t = 77°$ Fahr., Equation (7) will give, to nearest 0.01 mm.:

$d_1 = 0.04$ mm. for first stage, the smallest cone.
$d_2 = 0.02$ mm. for second stage, the middle cone.
$d_3 = 0.01$ mm. for third stage, the largest cone.

It is desirable to keep the separation sizes constant; and in case of any change in the temperature, the flow can be adjusted to offset this temperature effect, thus giving a constant, d, in Equation (7). It is seen from the formula that d varies as the square root of the flow. Then, by adjusting the flow to desired values, separation can be determined for corresponding smaller sizes.

As a practical procedure, however, this is not advisable. Duration of the test varies inversely as the flow. A flow of 48 cu. cm. per min. will give a lowest separation of 0.01 mm., and the actual run of the test through the elutriator will take nearly four times as long for a separation to a fineness of 0.005 mm. Of course, according to the formula, the law will also hold for higher flows—no doubt within limits—with larger separations and less time.

The results obtained by the elutriator are reliable especially when they are checked now and then by microscopic examination. This method is a great improvement in the accurate and rapid determination of grain sizes finer than the 200-mesh sieve compared with other methods used heretofore.

Microscopic Control

Microscopic measurements may involve assumptions which perhaps are not exact and which may influence the results, and yet it is the most reliable method available for observation and checking purposes. The microscope is very useful also to observe and study the shape and other characteristics of particles.

Periodically, microscopic measurements of the separation of the 200-mesh sieve and also of the three stages of the elutriator were made at Cobble Mountain in accordance with the method outlined[9] by Professor Lincoln T. Work.

The Hydrometer

The most rapid method, with reasonable accuracy, in determining the grain sizes finer than the 200-mesh sieve, known to the writer, is by means of the hydrometer developed by Dr. J. G. Bouyoucos.[10] Within almost an hour, one-third of the minimum time necessary for the elutriator, an analysis can be made of a soil sample by this method. The apparatus required is very simple and its cost is almost negligible compared with that of the elutriator. This method has many advantages, and it is being used in many places as the only means of determining the grain sizes of soil particles.

The hydrometer is so constructed that the graduation on its stem at the water surface will indicate the number of grammes of soil in suspension per liter of water in the graduate containing the hydrometer. As a precaution, however, the readings should be checked with various predetermined quantities of grammes of soil per liter of water, or with solutions of known concentration. The theory upon which this method is based follows also from Stokes' law as given by Equation (3). Substituting the values of $P_p = 2.72$, $P_l = 1.00$, $g = 981$, and $r = \frac{d}{2}$,

Bouyoucos, *Science*, July 1, 1927, Vol. LXVI, No. 1696, pp. 16–17; and "Making Mechanical Analyses of Soils in Fifteen Minutes", by J. G. Bouyoucos, *Soil Science*, Vol. XXV, No. 6, June, 1928, pp. 473–480.

$$d = 0.1033\,(vn)^{\frac{1}{2}} \qquad \text{(8)}$$

Equation (8) can also be used for *d,* in millimeters, with *n,* in centipoises. The value of *n* for any temperature can be obtained from tables of coefficients of viscosity; therefore, it only remains to find the value of *v* for the determination of *d;* thus,

$$v = \frac{\text{Distance, in centimeters}}{\text{Time, in seconds}} \qquad \text{(9)}$$

At different time intervals observations are made of the concentration (in grammes of soil per liter of water) of the suspension at the hydrometer center of buoyancy. From the beginning of the test to the time of any observation, during so many seconds, particles having diameters larger than a certain critical size are traveling by, or particles finer than that critical size are still in suspension above, the center of buoyancy. The traveled distance is taken from the water surface to the buoyancy center, but this is not constant for different concentrations of a suspension; neither is it necessarily the same for any two hydrometers. For each hydrometer a curve similar to Fig. 4 should be prepared. With distances obtained from Fig. 4, and the time, in seconds, as observed, the velocity is computed and Equation (8) is solved for *d.*

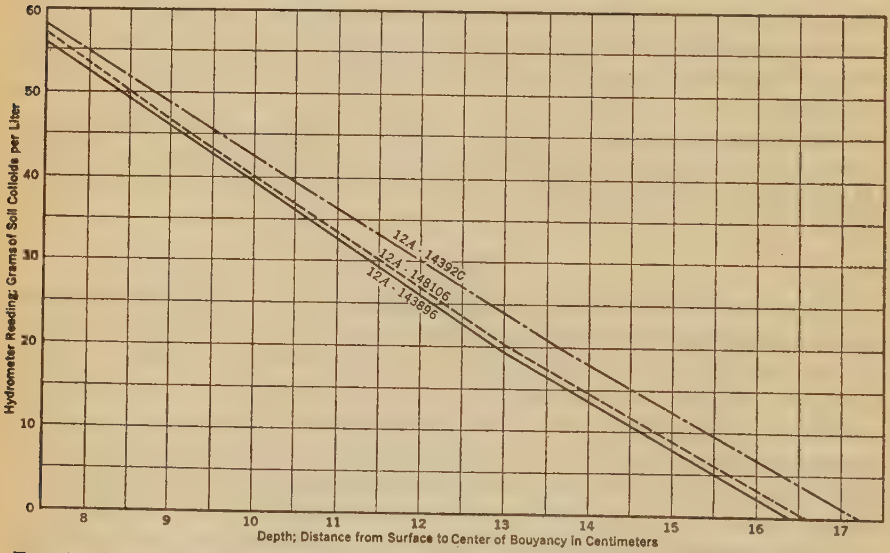

FIG. 4.—CURVES SHOWING DISTANCE FROM CENTER OF BUOYANCY TO WATER SURFACE, PLOTTED AGAINST GRAMMES OF SOIL PER LITER.

The hydrometer has been designed for a water temperature of 67° Fahr. = 19.44° cent. If water is used with another temperature it will be necessary to make a correction due to its change in density according to the formula,

$$R_o = \frac{s}{s-1} 1\,000\,(P_o - P_t) + R_t \ldots\ldots\ldots\ldots\ldots (10)$$

in which, R_o is hydrometer reading at 19.44° cent.; s, specific gravity of soil; P_o, density of water for 19.44° cent.; P_t, density of water at t° cent.; and R_t, hydrometer reading at t° cent.

The term, $\frac{s}{s-1} 1\,000\ (P_o - P_t)$, is the correction to be applied to the reading of the hydrometer at any temperature. The water has a maximum density at about 4° cent., and it decreases gradually as the temperature rises. The density of water below 4° cent.—in fact, below that of the working temperature—need not be considered. Whenever the temperature is below 19.44° cent., the correction will be negative, or with a minus sign, and *vice versa.* The correction term can be plotted for any value of specific gravity, from the relation:

$$C_t = 1\,000 \frac{s}{s-1} (P_o - P_t) \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

As a precaution, however, it is well to take hydrometer readings at different temperatures and check the theoretical correction curve. The corrected hydrometer reading gives the weight of particles finer than those of d for which the observation was made. This weight, divided by the total weight of the original sample, gives the percentage finer than d. With observations made at different time intervals, corresponding computations are completed and the gradation curve is plotted.

Some soils in their natural state contain elements which produce flocculation when the material is placed in pure water. In most cases this may be overcome by the use of a deflocculating agent (such as, ammonia or sodium oxalate). For local materials which showed a very slight, or no, tendency to flocculate, a fixed quantity (5 cu. cm. per liter) was used satisfactorily.

Gradation Procedure by Sieving and Hydrometer Method

The apparatus required for grading material by the sieving and hydrometer method follows:

One gyratory riddle with nest of Tyler sieves (Mesh Nos. 4, 8, 14, 28, 48, 100, and 200);
One 250-mesh sieve;
One motor, cup, and stirring device;
One glass cylinder graduated to about 1 100 cu. cm.;
One hydrometer graduated in grammes of soil colloids per liter of water at 67° Fahr.;
One centigrade thermometer (—10° to 110° cent.);
One stop-watch; and miscellaneous laboratory equipment, including wash bottle, balance, drying oven, etc.

The preliminary treatment entails five steps, as follows:

1.— Determine the moisture content of the moist soil sample to be tested, and weigh out the amount necessary to give about 35 grammes of — 200-mesh material.
2.— Place the sample in the stirring cup, washing out all particles from the weighing container with water; and fill the cup about three-fourths full with water and add 5 cu. cm. of ammonia or sodium oxalate ($Na_2C_2O_4$). Experiments with local materials showed that the 5 cu. cm. of dispersing agent gave satisfactory results in all cases.
3.— Place the cup in the stirrer, and stir for about 10 min.
4.— Wash the material through a 250-mesh sieve, drying the coarse fraction at 105° cent.
5.— Make a sieve analysis of the coarse portion (Sieve Nos. 4, 8, 14, 28, 100, and 200).

The sample is prepared for the hydrometer run in two steps, namely,

6.— Add the — 200-mesh material from the dry sieving to the — 250-mesh material in suspension from the preliminary washing; and
7.— Transfer the suspension to a liter graduate and fill with water to a volume equivalent to 1 000 cu. cm. plus the volume of soil used.

Then, the hydrometer run involves four final steps:

8.— Agitate the suspension by reversing the cylinder about ten times, covering the opening with the palm of the hand.
9.— Set the cylinder on a table and start the stop-watch immediately.
10.— Place the hydrometer in the cylinder.
11.— Read the hydrometer at 1, 2, 5, 10, 30, and 60 min., taking care to keep the hydrometer stem wet so that observations are taken on similar menisci.

Computation.—A computation based on an analysis of Sample *P*-11, Test *H*416, will be used to illustrate this procedure:

Moisture Content, by Step 1:

		Grammes.
Wet material + crucible	=	23.790
Crucible empty	=	12.874
Wet material	=	10.916
Dry material + crucible	=	20.954
Crucible empty	=	12.874
Dry material	=	8.080

$$\text{Percentage of dry material} = \frac{8.080}{10.916} \times 100 = 73.9$$

A total of 80 grammes of wet material was used; therefore, its equivalent dry weight was 80 × 0.739 = 59.12 grammes.

Sieving, by Step 5:

The weight of the + 250-mesh material to be sieved is 40.63 grammes. The analysis of the sample given in Table 2, shows that 40.57 grammes were recovered in the sieving. In other words, 40.63 − 40.57 = 0.06 grammes, lost in sieving.

TABLE 2.—ANALYSIS OF MATERIAL RETAINED ON A 250-MESH SIEVE

Mesh No.	Separation, in millimeters	Grammes retained	Cumulative grammes finer	Cumulative percentage finer
4	5.02	0	.....	100.0
8	2.60	0	.....	100.0
14	1.27	0	59.06	100.0
28	0.62	0.05	59.01	99.9
48	0.31	0.20	58.81	99.6
100	0.15	3.20	55.61	94.1
200	0.09	10.03	45.58	77.1
—200 (dry)	....	27.09	.....	.....
Total sample recovered from sieving	....	40.57	.....	.....

Hydrometer Run, Steps 8 to 11, Inclusive:

The arrangement of observations and computations for Steps 8 to 11, inclusive, is shown in Table 3.

TABLE 3.—OBSERVATIONS AND COMPUTATIONS

Elapsed time, in minutes (1)	Temperature, in degrees centigrade (2)	HYDROMETER READING Observed (3)	HYDROMETER READING Corrected (4)	Distance, in centimeters (5)	Velocity, in centimeters per second (6)	Viscosity, n (7)	Diameter, in millimeters (8)	Percentage finer (9)
1	19.2	27.3	27.2	11.95	0.199	1.025	0.0467	46.0
2	19.2	19.8	19.7	13.10	0.109	1.025	0.0345	33.3
5	19.2	12.0	11.9	14.45	0.0482	1.025	0.0230	20.2
10	19.2	9.0	8.9	14.95	0.0249	1.025	0.0165	15.1

60	19.0	4.3	4.2	15.80	0.0044	1.030	0.0069	7.1

These values (Table 3) are computed, as follows:

Column (1)	Observed
Column (2)	Observed.
Column (3)	Observed.
Column (4)	From Equation (10).
Column (5)	From Column (3), Table 3, and Fig. 4.
Column (6)	From Columns (1) and (5), Table 3, and Equation (9)
Column (7)	From Fig. 5.
Column (8)	From Equation (8).
Column (9)	Column (4) Table 3, divided by total sample (59.06 grammes).

Plotting.—Plot the hydrometer grading, together with the sieve analysis showing the particle size, in millimeters, against the cumulative percentage passing a given size of sieve. (See Fig. 6.) From the grading curve pick off the 10% (effective) size, and the 60% size and compute the uniformity coefficient, by dividing the latter by the former.

COMPARISON OF ELUTRIATOR AND HYDROMETER METHOD RESULTS

Many comparisons have been made of the results obtained by the elutriator and the hydrometer methods at Cobble Mountain. The hydrometer gradation curves, in the lower limits, are invariably above those of the elutriator, thus showing a higher percentage of finer particles. (See Fig. 6.) Logically, it

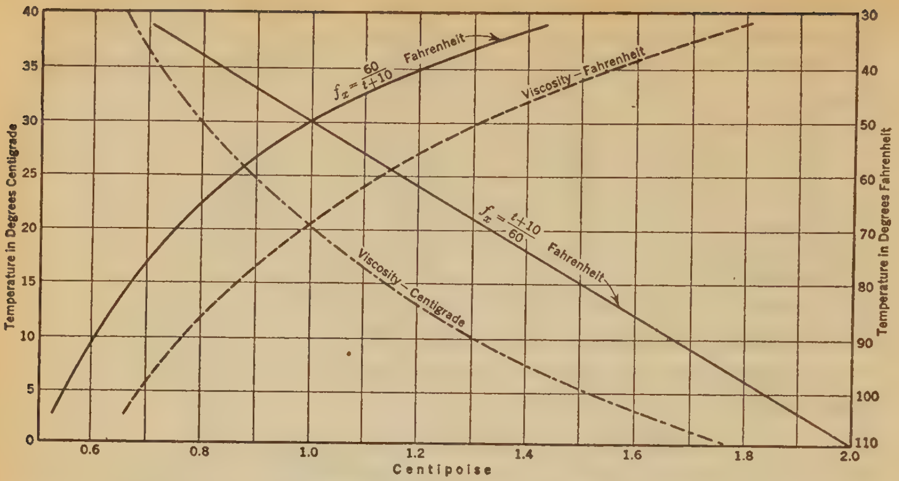

FIG. 5.—RELATION BETWEEN VISCOSITY AND TEMPERATURE FACTOR.

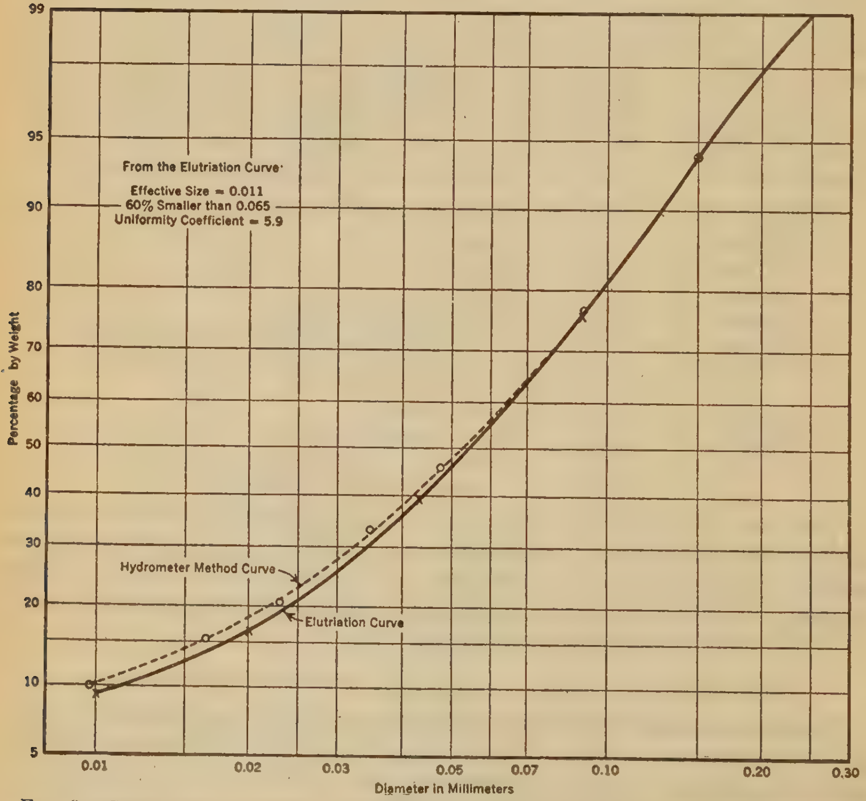

FIG. 6.—COMPARISON OF GRADATION BY THE ELUTRIATION AND HYDROMETER METHOD.

should be the reverse, as one would think that some of the fines would undoubtedly go down with the larger particles, thus resulting in a coarser curve. Sometimes there is a small amount of sedimentation on the shoulder of the hydrometer weighing it down and causing a smaller hydrometer reading. This also would result in a coarser curve.

The application of a certain correction to the fundamental formula of Equation (3) has been proposed[11] by Mr. H. A. Lorentz, in order to take care of the increased force of friction due to frictional retardation of particles falling contiguous to the cylindrical glass wall. For hydrometer gradation purposes, however, this correction is entirely insignificant. Stokes' law gives the vertical movement of the particles; their diagonal motion, if any (especially in the lower portion of the gradation), will result in slightly higher values. Dr. Bouyoucos suggests a correction of —1 for hydrometer readings below 10 grammes per liter.

Both the elutriator and hydrometer methods are based on Stokes' law which considers particles as spherical in the derivation of the formula, and too many flat bodies in the sample will give unsatisfactory results in both cases.

The hydrometer method described herein will give reasonably accurate results, at least for the gradation of hydraulic-fill dam materials, for readily dispersible and granular soils. Undoubtedly, this method is very useful and of great assistance during periods when the results are necessary in the shortest time possible. Due to its many advantages it has become very popular and is being used in almost every soil analysis laboratory. However, the method of carrying out the test has not been standardized, as evidenced by discussions with other engineers and in the comparison of results obtained for the same soil sample in different laboratories. The tests at the Cobble Mountain Laboratory were made according to the theory and method of procedure outlined in this paper.

TURBIDITY

The standard turbidity test method can be used in estimating the percentage of a certain size of fine particles in a sample. This is only a rough approximation, and since the introduction of the aforementioned hydrometer method it has lost its value. If no hydrometer can be obtained, however, the turbidity method may be used to advantage.

Curves of particle diameter against distance below water surface are plotted from Equations (8) and (9) for various values of t. They indicate the minimum depth of various sizes of particles below the water (temperature, 10° cent.) surface after t min. of settling. In Fig. 7 the two horizontal curves give the turbidity of two different concentrations after various time intervals, t, during settling. On the right-hand side of the diagram are shown the corresponding readings of turbidity, in parts per million.

The turbidity readings will depend on various factors, such as: (1) The personal equation of the observer, especially the eyesight; (2) the intensity of the daylight, or the lack of it; shadows on the sample; (3) the shape of the particle in suspension, whether spherical or flat; (4) the color of the sample; (5) presence of organic matter in the sample; (6) temperature effect; and (7) flocculation of the material. Even with these factors, however, for the same observer and under identical conditions, there will be, according to Fig. 7, a definite relation between percentage under a certain size of fine particles and the turbidity reading of the same material.

---

[11] "Colloid Chemistry", The Svedberg, 1928, p. 147.

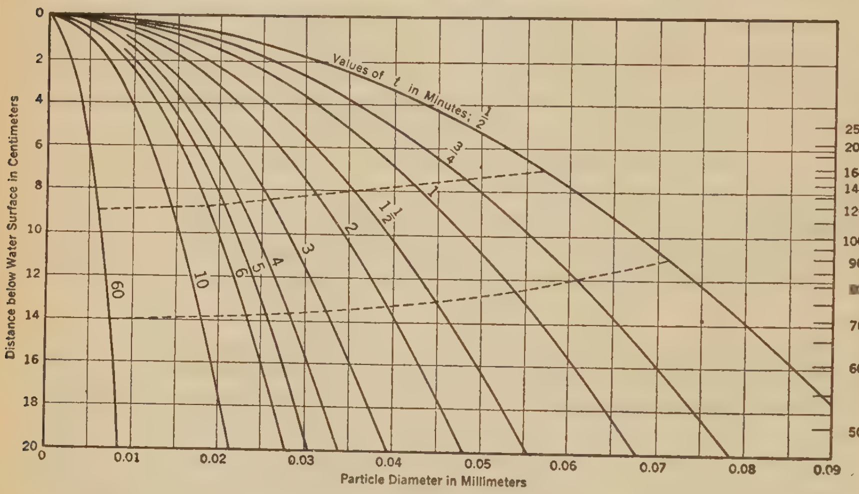

FIG. 7.—TURBIDITY CURVES SHOWING THE RELATION BETWEEN TURBIDITY AND STOKES' LAW.

Since the percentage finer than 0.01 mm. was used as a criterion, an attempt was made to find the relation between that percentage and the turbidity reading of the same material. The apparatus and the method of procedure are essentially the same as that used by the United States Geological Survey.[12]

The original concentration can be expressed in grammes of soil per liter of water. The turbidity reading is in parts per million and this is reduced to grammes per liter. This, then, divided by the original concentration, gives the percentage of original soil held in suspension at the time of observation. This ratio is called the percentage of turbidity.

A careful analysis of the same soil sample is made by a dependable method and the gradation is plotted. The percentage, from the gradation curve, finer than 0.01 mm. is divided by the percentage of turbidity, and the result is called the turbidity factor. When the percentage of turbidity and the turbidity factor of the same type of material are known, the product of the two will give the percentage of material finer than the particular size for which the factor was obtained.

Unless the material is completely broken up in the concentration while the turbidity is being taken, the turbidity reading will be very low. In some of the tests made at Cobble Mountain Reservoir of foreign samples which flocculated, it was found that the actual turbidity percentage obtained after complete dispersion of the material in suspension was as high as four times the values obtained before deflocculation. (See Table 4.)

---

[12] "Measurements of Color and Turbidity in Water," *Circular 8*, Div. of Hydrography, 1902.

Readings were made 2 min. after the stirring had stopped. Various turbidity readings of the same sample were taken at intervals varying from 30 sec. to 1 hour after the stirring had stopped, and it was discovered that there was only a slight difference in the turbidity readings during the first hour of settling after the first 2 or 3 min. Evidently, the large particles, in the early stages of settling (which were above the platinum wire) had only a slight effect in reducing its visibility.

TABLE 4.—TURBIDITY FACTORS OF VARIOUS SAMPLES TESTED AT COBBLE MOUNTAIN RESERVOIR FOR PERCENTAGE OF PARTICLE SIZES FINER THAN 0.01 MILLIMETER

Location of dam	Location of samples	Number of tests made	Percentage of material finer than 0.01 millimeter, by elutriation	Percentage of turbidity	Turbidity factors

ORGANIC MATTER

Organic matter is present near the surface in almost all borrow-pits, and shallow pits will have a higher percentage than deep ones. As a rule the surface soil of a dam site is sluiced, especially within the core area, and contains a high percentage of organic matter. The surface soil at the site of Cobble Mountain Dam varied from scarcely any to about 6 ft. in depth, and the average of sixteen samples showed about 8 per cent.

The determination of the percentage of organic matter is one of the important requirements. The organic matter that settles in the pool with the core material is usually very fine. It will tend to prevent the drainage of the core; it will affect the determination of the percentage of voids by moisture content and possibly the percolation test results; and it is often responsible for loss of material during elutriation tests. The effect of organic matter on computations of the percentage of voids (Equation (1)) may be expressed as follows:

$$V_t = 100\left(1 - \frac{W}{B\,s_t}\right) \qquad \text{(12)}$$

and,

$$V_o = 100 - \left(\frac{W}{B}\right)\left(\frac{a}{s_o} + \frac{100 - a}{s_i}\right) \ldots\ldots\ldots\ldots\ldots (13)$$

or, from Equations (12) and (13),

$$V_o = V_i - a\left(1 - \frac{V_i}{100}\right)\left(\frac{s_i}{s_o} - 1\right) \ldots\ldots\ldots\ldots\ldots (14)$$

in which, V_o is the percentage of voids observing effect of organic matter; V_i, percentage of voids neglecting effect of organic matter; s_o, specific gravity of organic matter; s_i, specific gravity of soil particles; a, percentage of organic matter by weight; W, weight of sample, in grammes; and B, volume occupied by sample, in cubic centimeters. The last term on the right-hand side of Equation (14) is a correction because of organic matter to be applied to the computations of percentage of voids, V_i, as ordinarily computed.

Assuming that $s_i = 2.72$, and $s_o = 0.60$, Equation (14) becomes:

$$V_o = V_i - 3.53\, a \left(1 - \frac{V_i}{100}\right) \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

It is interesting to study the relation between V_o and V_i for various percentages of organic matter, according to Equation (15). For instance, for a 3% organic matter ($a = 3$), with the computed percentage of voids, $V_i = 53$, it is seen that the actual percentage of voids is only 48. In other words, 3% of organic matter in the core material makes a difference of 5% in the computations of the percentage of voids of the material, had the organic matter been neglected. Equation (15) will apply for any other values of s_i and s_o and for their different values curves can be plotted to facilitate computation.

Organic matter can be determined by the method of "loss on ignition." This method is not reliable, unless the test is run carefully because minerals may decompose during the test if the sample is overheated, thus giving higher results for organic matter.

The albuminoid ammonia method was used for a few determinations of organic content, but was discarded later since reasonably accurate results could be obtained more easily and in a shorter time by igniting a sample.

Colorimetric tests for the determination of organic matter, similar to those made for organic impurities in concrete sands, were tried. Due to the fact that the cores of hydraulic-fill dams have a higher percentage of organic matter than concrete sands, a smaller ratio of sample material was used. It may be possible to shorten and simplify this method so that it can be used to advantage in the determination of organic content of materials for hydraulic-fill dams.

GRADATION OF CORE MATERIALS

With due respect to the difference in opinions regarding the many factors affecting the suitability of the core material other than its size gradation, the writer believes that one of the most important criterions to decide this suitability is the grain size and the gradation of the core material.

There has been much controversy among engineers in regard to the proper sizes of the core material for hydraulic-fill dams. Every engineer who has built a successful dam is inclined to insist that the sizes of his core are the proper ones to be used. Unfortunately, every engineer has his own method of determining gradation, and the question arises as to whether the different results give a fair basis of comparison.

Numerous samples of core and borrow materials from important hydraulic-fill dams were secured and tested at the Cobble Mountain Reservoir with the same method and under the same conditions, so as to make the results comparable. In Fig. 8 the numbers in parentheses denote the number of samples tested and averaged in each case for the resulting curve. The Alexander Dam, at Kauai Island, Hawaii, collapsed in 1930, during construction. The gradation shown for this dam is that of the material before failure. The heights of these dams are: Blue Ridge, Ga., 170 ft.; Calaveras, Calif., 225 ft.; Cobble Mountain Dam, Mass., 263 ft.; Conklingville, N. Y., 95 ft.; Garza, Tex., 80 ft.; Gatun Dam, Canal Zone, 115 ft.; Germantown, Ohio, 110 ft.; Cambria Steel Company Dam, Johnstown, Pa., 95 ft.; City Dam, Johnstown, Pa., 70 ft.; Rocky River Dam, New Milford, Conn., 92 ft.; Saluda, S. C., 208 ft.; Sherman Dam, Monroe, Mass., 100 ft.; Somerset, Vt., 110 ft.; Swinging Bridge Dam, Forestburg, N. Y., 135 ft.; and Wichita Falls, Tex., 100 ft.

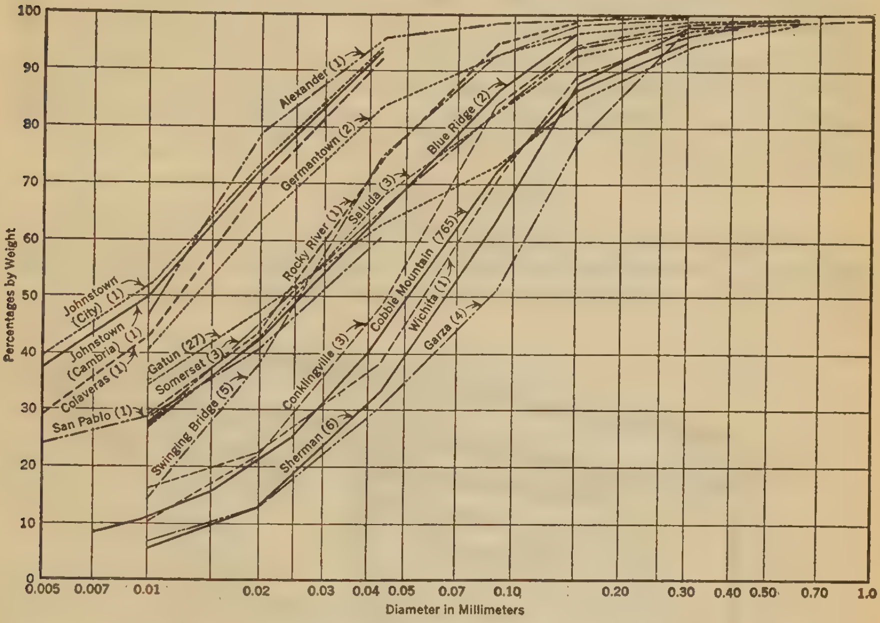

FIG. 8.—SUMMARY OF GRADING ANALYSES, MADE AT COBBLE MOUNTAIN RESERVOIR OF CORE SAMPLES, FROM VARIOUS HYDRAULIC-FILL DAMS.

Scarcely, if ever, will the core material of a hydraulic-fill dam have the same grain sizes and gradation throughout the body of the core. One sample, or a few samples, of any core will not necessarily correspond to a representative average of the entire core material. It is necessary, therefore, to make frequent and numerous gradation analyses in order to obtain a fair average gradation curve for the entire core of a dam. The writer doubts whether the gradations given in the summary sheet (Fig. 8) will really represent the average of the entire core of any dam represented by the analysis of any one of its samples. Unfortunately, it was impossible to secure the desired number of samples for every dam. Otherwise, the summary sheet, Fig. 8, is believed to be of real value for a comparison between various core material gradations, since no error is present due to difference of method and to personal equations. It is well to call attention here to the fact that each engineer plots gradation curves differently. The gradation plotted in the first quadrant, with "diameter sizes, in millimeters" increasing from left to right as abscissas and "percentage of material finer by weight" increasing from the bottom upward as ordinates, seems to be the most logical.

Coefficient of Friction

The beach materials of hydraulic-fill dams consist generally of clean sand and gravel. The coefficient of friction of these materials is of great importance in design, but, unfortunately, no reliable data are available.

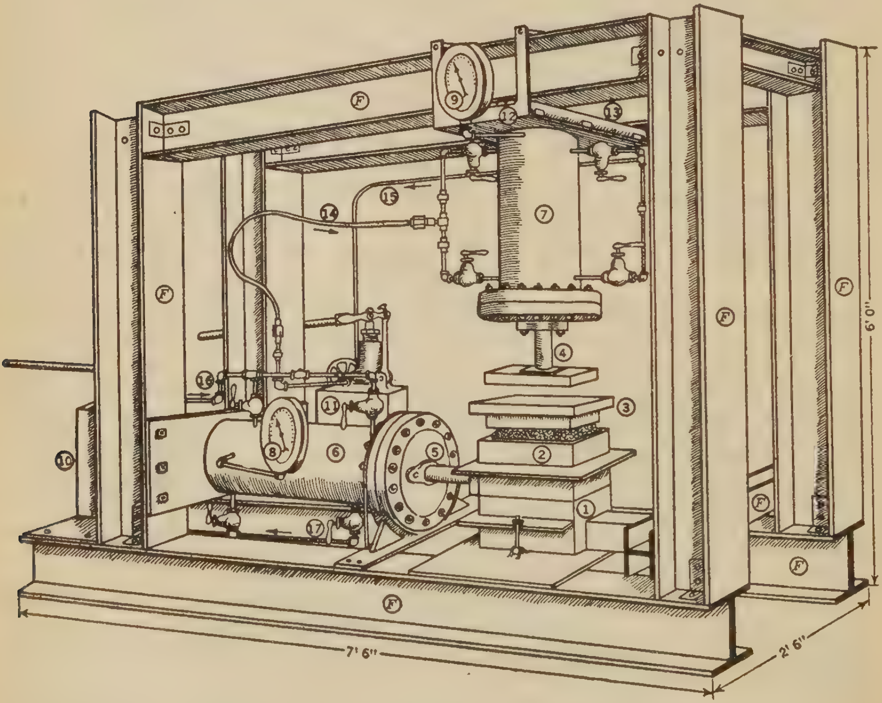

Fig. 9.—Apparatus for Determining Coefficients of Friction.

The apparatus used for measuring the coefficient of friction of materials at Cobble Mountain (see Fig. 9) was specially designed for the purpose. It consists of a rigid steel frame, *F*, electrically welded throughout, weighing about 2 tons. Within this frame the essential working parts (labeled in Fig. 9) are, as follows: Vertical pressure is applied to the material within the sample boxes (1) and (2), by means of the loading block (3), which, in turn, gets its force from the piston shaft (4), operated by water under pressure within the cylinder (7). This hydraulic pressure is obtained by a hydraulic hand-pump (11), by way of the feed-pipe (14). The horizontal force required to shear the sample is applied to the upper box (2), in a similar manner by pump (10), feed-pipe (16), horizontal cylinder (6), and piston shaft (5). Hydraulic pressure in both the horizontal and vertical cylinders is recorded on 1 500-lb. pressure gauges (8) and (9), respectively. The vertical cylinder is mounted on a carriage (12), holding rollers (13), to permit horizontal movement as shear takes place. As the piston within the cylinders moves in either direction, water is forced back to the pumps through return pipes (15) and (17) for further use.

The procedure for determining coefficients of friction is:

(*a*) Weigh out about 100 lb. (dry weight) of sample and place enough of it in the lower sample box (1), agitating the material in the box under water for complete saturation.

(*b*) Place the upper half of the sample box (2) into position and continue placing the sample material to the top of the box in the same manner as in Step (*a*).

(*c*) Allow the sample material to drain partly for 5 to 10 min. Place the loading platform (3), leaving sufficient clearance between the platform and the sides of the sample box.

(*d*) Take measurements of the height of the sample in the box and record.

(*e*) Apply the vertical load (4) gradually on the sample, to pressure (9) desired for test.

(*f*) Allow the sample material to consolidate for 5 to 15 min., keeping the pressure over it constant by a slight pressure applied to the handle of the pump (mentioned in Step (*e*)).

(*g*) Release the vertical pressure, jack the two sample boxes apart about $\frac{1}{4}$ in., and leave them blocked apart.

(*h*) Apply vertical pressure as in Step (*e*) and allow the material to consolidate further.

(*i*) Remove the blocks between the sample boxes.

(*j*) Measure the height of the compressed sample material (for computing the consolidation) and record.

(*k*) Apply pressure slowly by means of the horizontal piston (5) to the upper half of the sample box until there is no increase in the pressure observed on the corresponding gauge (8); any additional horizontal pressure at this point would cause the upper box to slide which would indicate that the sample has sheared.

(*l*) Observe both the horizontal (8) and vertical (9) gauge readings at this point, Step (*k*), and record.

(*m*) From the foregoing records compute:

$$L = \frac{G A_p}{A_s} \qquad (16)$$

in which, L is the vertical pressure, in pounds per square inch; G, the vertical gauge reading; A_p, the area of the piston; and A_s, the area of the sample. Next compute the coefficient of friction from the relation: Coefficient of friction $= \frac{\text{horizontal gauge reading}}{\text{vertical gauge reading}}$. Finally, the percentage of voids is determined from,

$$V = \frac{100}{B}\left(B - \frac{W}{s}\right) \qquad (17)$$

in which, B is the measured volume of sample; s, the specific gravity of material; and W, the dry weight of sample.

(*n*) Release the pressures and remove the sample.

(*o*) Make independent and complete coefficient-of-friction tests, repeating Steps (*a*) to (*n*) for various desired vertical pressures up to 400 or 500 lb. per sq. in.

(*p*) Plot the results with the coefficient of friction as ordinate, and vertical pressure, in pounds per square inch, as abscissa.

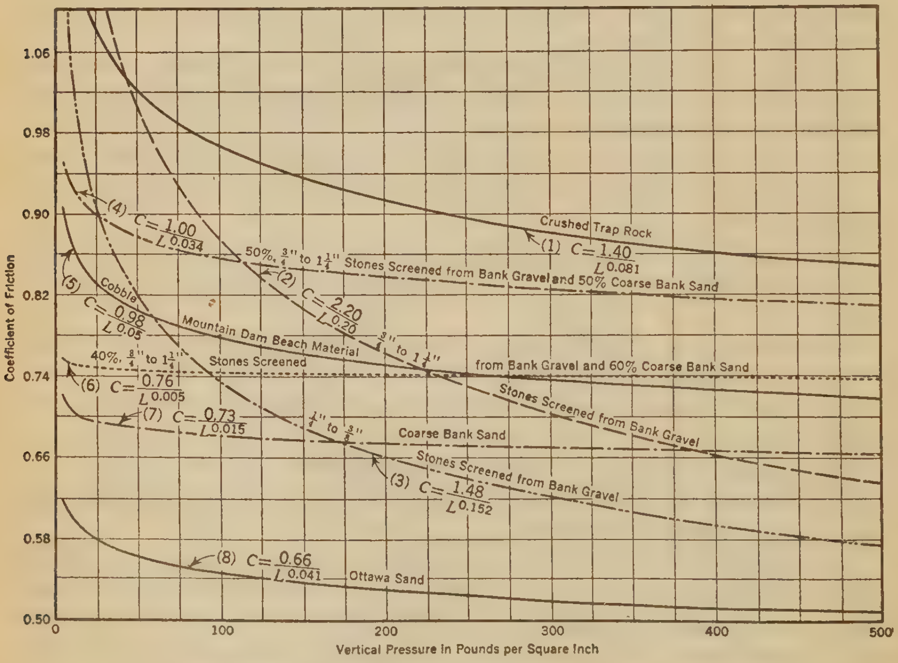

FIG. 10.—COEFFICIENT-OF-FRICTION CURVES FOR VARIOUS MATERIALS.

Curves resulting from about 550 coefficient-of-friction tests made at Cobble Mountain Reservoir, are given on Fig. 10. It will be seen that the coefficient is not constant, but is expressed by the general formula:

$$C = \frac{k}{L^m} \quad \text{.............................} (18)$$

in which, C is the coefficient of friction; k, the constant; L, the vertical pressure in pounds per square inch; and m, the exponent of L.

It is further seen that k, the constant for any one material, varies from 0.66 to 2.20, and that values of m, the exponent of L, range from 0.005 to 0.20, depending on the characteristics of the material tested.

Due to the fact that the beach materials of a hydraulic-fill dam are placed by water and that after construction they are never absolutely dry, the test materials were placed by water in the sample boxes, and, after draining all free water, the tests were conducted while the material was wet. The data given in Fig. 10 are based on the foregoing conditions.

Although primarily interested in the coefficient-of-friction values of the beach and core materials of Cobble Mountain Dam, more than 200 tests were made on outside materials consisting of various local and foreign samples of sand, gravel, crushed trap-rock and screenings, and Ottawa sand. The coefficients for the materials in question are affected by their particle sizes, hardness, percentage of voids, moisture content, particle shape, and gradation.

The conclusion drawn from the tests at Cobble Mountain Reservoir is that, other factors remaining the same, for any given material, higher values of the coefficient of friction are obtained by: (1) Larger particle sizes; (2) harder material; (3) smaller percentage of voids; (4) dryer material; (5) particles of more angular shapes; and (6) better graded material, or the combination of Factors (1) and (3).

The tests showed conclusively that larger particle sizes gave higher coefficients of friction. The interlocking effect of stones seems to be an important factor. In the rock toes of Cobble Mountain Dam where the maximum particle sizes with irregular shapes are about 20 cu. yd., it is difficult to estimate the increase in the coefficient-of-friction value.

The hardness of material is important. No material was tested, that did not show the effect of crumbling or breaking after shearing under vertical pressure. Softer materials crumbled more, thus causing considerable decrease in particle sizes; the larger sizes crushed more than the smaller ones, and irregular-shaped particles more than the rounded ones.

The curves in Fig. 11 give the amount of crumbling for tests on different materials at various pressures. The results are from gradings made on samples taken at the shearing plane before and after a test. The increase in percentages plotted are based on the finest sieve of the size range shown for each material, except for the coarse bank sand and the crushed trap-rock screenings, for which No. 28 (0.62-mm.) and No. 14 (1.27-mm.) sieves were used, respectively. A new sample of the original material was used for each pressure. In every case, it is seen that the crushing effect increases with an increase in pressure, thus reducing the particle sizes. Undoubtedly, this is greatly, if not entirely, responsible for the decrease in the coefficient-of-friction values for higher pressures (Fig. 10).

For the same pressure a given material with a smaller percentage of voids yielded a higher value for the coefficient of friction. However, there is a limit to minimum percentage of voids because, under a given vertical pressure, the percentage of voids of a material will eventually become almost constant. Slight variation in the consolidation under the same pressure may be due to the final arrangement or self-placement of the particles, or, perhaps, to the crumbling of particles to a certain extent.

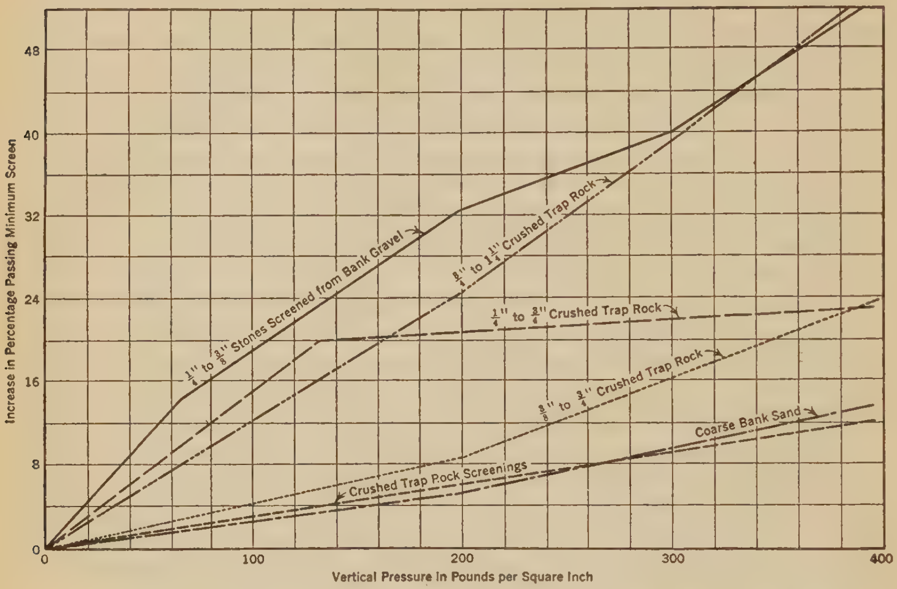

FIG. 11.—CURVES SHOWING AMOUNT THAT MATERIAL CRUSHED DURING TESTS FOR COEFFICIENT OF FRICTION.

When the particles of the material carrying the load are wet, the moisture seems to act as a lubricant, and there is a decided decrease in the value of the coefficients, especially at low pressure. The same material dried and tested for coefficient of friction under a given vertical load gives higher values. In Fig. 12, which illustrates this point, the increase in the coefficient of friction is based on the coefficient of the material in a wet condition; that is, the surfaces of all particles are entirely covered with water.

The more irregular the shape of particles the more pronounced is the effect of interlocking, resulting in increased resistance for friction. The easy crumbling of the sharp edges of particles with angular shapes may offset this interlocking advantage somewhat. Unless the material is hard, the sharp corners may not prove advantageous. The more uniform the particle sizes the higher is the percentage of voids. Well-graded beach material containing coarse particles has smaller percentages of voids and will have higher friction values.

The foregoing data are by no means all that are desirable as to the coefficient of friction of materials in hydraulic-fill dams. Unfortunately, at Cobble Mountain Reservoir it was not possible to make further investigations along this line. In this large field much more reliable information is necessary to determine the characteristics of various materials, in order to understand fully the behavior of the coefficient of friction.

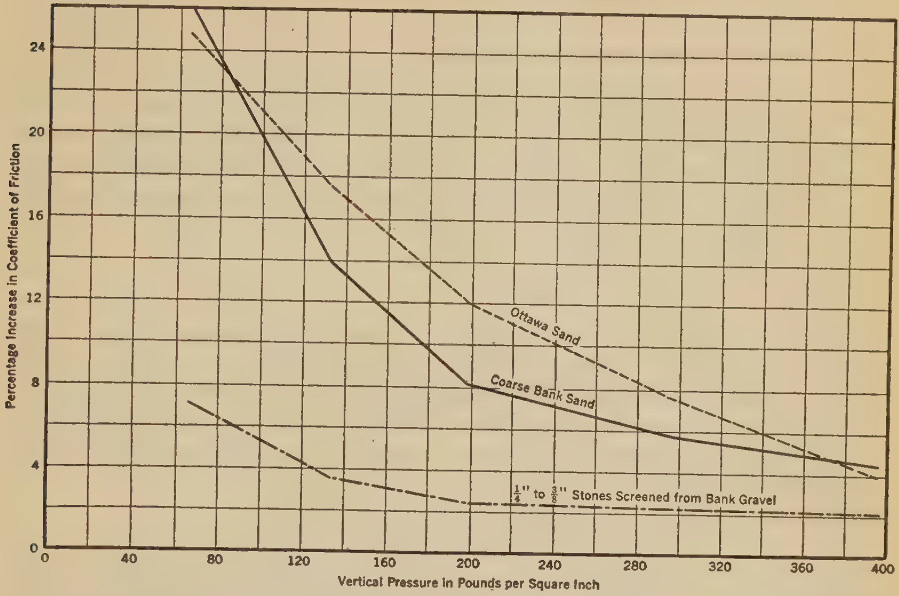

FIG. 12.—CURVES SHOWING INCREASE IN THE COEFFICIENT OF FRICTION DUE TO CHANGE FROM WET TO DRY CONDITION.

PERCOLATION

The percolation, or the permeability, test is one of the practical criterions of the ultimate behavior of the dam; and, therefore, this test is important and should be carried on with the greatest care.

The purpose of the gradation, or the determination, of the grain size of the core material is to ascertain whether the material has enough fines so that it will be impervious, or reasonably so, and whether it is coarse enough so that it will drain and solidify within the near future. As will be seen elsewhere in this paper, the effective size of the material, obtained from the gradation curve, will be useful in estimating its coefficient of permeability. It is better, however, to determine the coefficient of permeability directly rather than rely on gradation alone, as seepage through a core material will depend not only on the effective size and gradation of its materials, but also on its percentage of voids, its percentage of organic matter, its resistance to consolidation, or the shape and toughness of the particles, and on its percentage of clay, especially within the colloidal ranges, etc.

The velocity of seepage through fine core material is so slow that units, such as centimeters per second, or feet per second, will result in small quantities. It is advisable to express this velocity in meters per day, which will result in numbers that are more convenient. The coefficient of permeability, K, in meters per day, is also equal to cd^2, in which c is a constant and d is the effective size of the material.

As the normal ground-water temperature is about 10° cent., and as the change in temperature will affect the velocity, it is better to base the coefficient of permeability on 10° cent., or 50° Fahr. In dealing with the determination of the values of K, 45% voids consolidation was used as a basis. The fundamental formula used in determining the velocity of seepage through soils is known as Darcy's law:[13]

$$v = K \frac{H}{l_p} \quad \dots\dots\dots\dots\dots\dots\dots\dots (19)$$

in which, v is the velocity of flow; K, the coefficient of permeability; H, the head causing the flow; and l_p, the length of the path of percolation. Since H and l_p are known, or can be assumed, the value of K is required. Due to the fact that the experiments to determine the value of K require long periods of time and constant watching, attempts have been made to develop short-cut methods.

STAND-PIPE PERMEAMETER

Both the vertical capillary rise[14] and the horizontal capillary flow[15] methods of measuring permeability of soil were tried at Cobble Mountain Dam and were found unsuitable for core materials in a hydraulic-fill dam.

The simplest method of measuring the permeability of a soil is by a stand-pipe permeameter. In the apparatus used at Cobble Mountain shown in Fig. 13 the core material, in a saturated state similar to that in the dam, is placed in a glass tube and immersed in a pail of water. The head causing flow is measured from the top of the column of water in the stand-pipe to the level of the water in the pail. By means of a stop-watch the rate of fall of the water column in the stand-pipe was observed, and its volume was obtained when the bore of the stand-pipe had been determined. From the moisture content of the sample its percentage of voids is computed.

The coefficient of permeability, K, in meters per day, is computed from the equation:

$$K = 1\,989.44 \frac{A\, l_p}{A_s\,(T_2 - T_1)} \log \frac{H_1}{H_2} \quad \dots\dots\dots\dots\dots (20)$$

in which, A is the cross-section area of the stand-pipe; A_s, the cross-section area of the sample; l_p, the thickness of the sample; T, time; and H, the head that causes flow; that is, H equals height of water in the stand-pipe, H_1 at the beginning, and H_2, at the end, of the run. Equation (20) is derived from Darcy's law and is reduced from the observed temperature to its value at 10° cent. by means of Fig. 5. During any of the tests—for the same material, with the same percentage of voids, and whatever the value of H_1 in Equation (20)—K remained constant, provided the sample maintained structural equilibrium during the runs.

FIG. 14.—LARGE PERCOLATOR.

It should be remembered that the stand-pipe permeameter has a low head and the sample to be tested is very small. Furthermore, there is a chance for the water to flow more freely contiguous to the inside wall of the glass cylinder.

LARGE PERCOLATOR

This apparatus (Fig. 14), designed by the late Allen Hazen, M. Am. Soc. C. E., can be used with a high head of water pressure. It has a capacity for core material of about 1 cu. ft., which is sufficient to reduce the effects of slight local variations in the sample. It was lined with concrete forming a collar near the top of the sample to check seepage contiguous to the inside surface (see Fig. 14).

The sample is placed in a saturated state as it comes from the core, and is supported and covered by sand filters. After a period of initial settlement (about 24 hours), the container is sealed and the water pressure is applied at the top of the sample in gradually increasing amounts, to the desired limit. A maximum head of water of about 60 ft., was used at Cobble Mountain Reservoir.

In order to avoid the effect of a possible film of fines at the surface of the sample, the head was measured by a differential mercury manometer connected at points, 1 ft. apart, lying within the sample. The readings gave a direct measurement of the head causing the flow through 1 ft. of the material, or the value of $\frac{H}{l_p}$ in Equation (19). The discharge was measured at convenient intervals, when the temperature was observed.

The values of K in Equation (19) decreased rapidly during the first few hours of the test, and continued to decrease slowly for a long time. The initial tests were carried on over a period of from two to three months, when the coefficient of permeability became nearly constant. It was found, however, that satisfactory comparable tests could be terminated in a week. The initial rapid decrease was due to the fact that the applied pressure produced a decrease in the percentage of voids which was accompanied by settling of the sample. All values of K were reduced to 10° cent. for comparison. The voids of the core sample were found at the beginning and at the end of the test, by moisture-content determinations.

The large percolator is satisfactory for the determination of the coefficient of permeability for a soil sample at a single percentage of voids, but it is not suitable for the measurement of consolidation, or the corresponding variations in the coefficient of permeability.

STANDARD COMPRESSION APPARATUS

The best device for the determination of the relation between K and the percentage of voids, is that by Professor Terzaghi, described by Professor Gilboy in the paper previously cited.[15] This device (called the standard compression apparatus) will measure not only the rate of consolidation and compressibility of a soil sample under a given load, but also its permeability at different stages of consolidation. No description of the apparatus is necessary here, as it has been described often and is fairly well known. The loading system is made in such a way that the compressibility of core material can be measured with a load of 200 lb. per sq. in., which is about the maximum pressure in the Cobble Mountain Dam.

After the sample is placed in the machine, the stop-pin is removed and consolidation is allowed to take place under the weight of the piston. When this is practically complete, the stand-pipe connection is made. Increments of weight are applied in order to give the desired pressures up to 200 lb.

per sq. in. At each loading observations are made to determine the rate of consolidation under that load and sufficient time is allowed for complete consolidation. The permeability after complete consolidation is observed for each loading.

The increments of weights are removed in the order that they were placed, and sufficient time is allowed for complete expansion between the removal of each load. Additional observations may be made for permeability at this time.

The average of the readings of two Ames dials is used for computing the consolidation. The coefficient of permeability is computed from Equation (20) and reduced to its equivalent value at 10° cent. The following data are obtained for a given material: (*a*) The rate of consolidation for each loading; (*b*) the compressibility and expansion; and (*c*) the coefficient of permeability.

Numerous tests were run with the standard compression unit and valuable data obtained. It was unfortunate, however, to note that the coefficient of permeability of the same sample and for the same percentage of voids obtained by the standard compression apparatus was invariably lower than, and in some cases one-half, the results obtained from the large percolator. The variation of the results, for each apparatus and for different percentages of voids, was consistent. There was no apparent reason to doubt the results obtained by the large percolator because no difference was found in the value of K for different values of H. The sample of the standard compression apparatus is so small that a personal equation or any slight cause may result in a great difference in the result of the test. The following might account for the small values of K obtained by the standard compression apparatus: (*a*) The inside area of the piston bearing on the top porous plate is 28.7 sq. cm., whereas the area of the sample is 38.1 sq. cm.; thus, the water of about 25% of the sample area is forced to come in a diagonal direction; (*b*) there is a possibility that the top porous plate may become clogged to a certain extent; and (*c*) the puddling of the sample in placing it in the cylinder may cause segregation.

The results obtained for the coefficient of permeability of fine core materials are so small and subject to so many different factors that even, say, about 100% variation between two different apparatus cannot be considered serious.

PERCOLATION AND PERCENTAGE OF VOIDS

In the numerous experiments for the coefficient of permeability of any one material, K remained constant for any value of H, provided the percentage of voids of the material remained constant and the sample maintained structural equilibrium, but it showed a decided change due to variation in the percentage of voids.

The curves of Fig. 15 show the relation between the value of K and the percentage of voids of several core samples. This relation can be expressed by the formula,

$$K = c\,p^{m} \qquad (21)$$

in which, K is the coefficient of permeability, in meters per day, and for $t = 10°$ cent., c, is a constant, and p, the percentage of voids divided by 100. The value of c varied from 2.86 to 0.48 and the value of m, from 5.40 to 7.20.

For the same material, it can be stated that K varies approximately as the sixth power of the percentage of voids. Thus, the value of K for 50% voids compared with that of 40% will be about $\left(\frac{50}{40}\right)^6$, or 3.8 times. This relation, derived from tests on local core samples, will be reasonably accurate for local material. The relation might be similar for other core materials, provided their grading and character are similar.

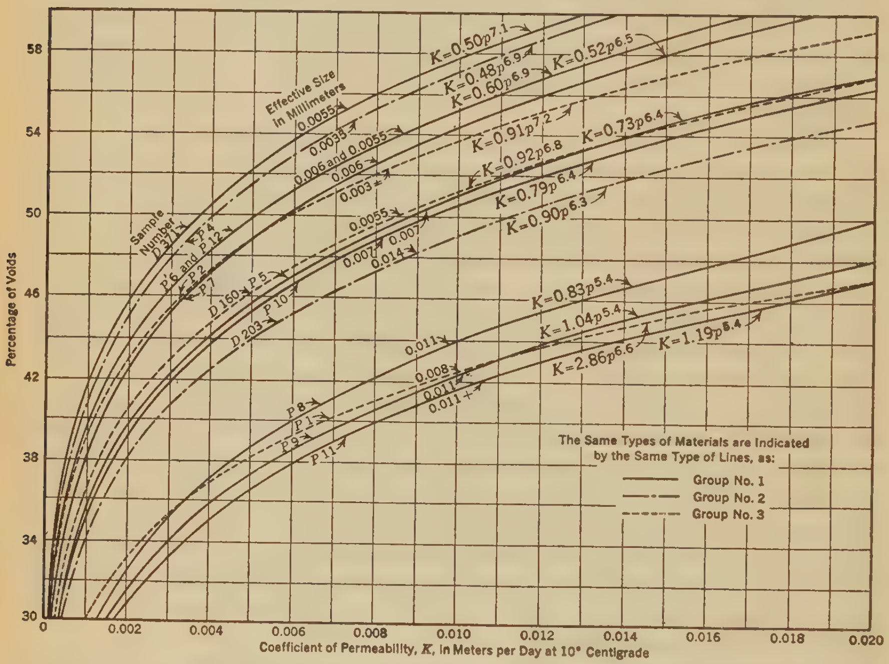

FIG. 15.—PERCENTAGE OF VOIDS PLOTTED AGAINST COEFFICIENTS OF PERMEABILITY FOR VARIOUS MATERIALS AND EFFECTIVE SIZES.

In Fig. 15, the values of K point out three distinct characteristics; namely, that they (1) differ considerably for different materials; (2) vary most decidedly according to the effective size of each sample of the same character of material; and (3) vary according to the slope of the gradation curves of the same character of material even if the materials may have the same effective size.

Fig. 16 gives the gradations of the materials of the curves of Fig. 15. Comparing $P5$ and $P10$, both being the same kind of material and having the same effective size—0.007 mm.—and the value of m being 6.4 in both cases, the value of c for $P5$ is 0.73, and for $P10$, it is 0.79. On Fig. 16, it is seen that $P5$ is finer than $P10$ with a difference of about 0.005 mm. in their grain sizes for the entire range between the 35% size and the 60% size, or the $P10$ grain sizes are 16% larger than $P5$ in that range. This causes about 8% variation in the rate of percolation of the two samples.

A similar comparison of $D371$ with $P12$ shows that the latter has a coefficient of permeability about 40% greater than the former. From Fig. 16 it is seen that the curve of $P12$ is coarser from the 20% to the 60% size. The particles in this range have an average difference in diameter of about 17 per cent. Furthermore, for the same range the particle sizes of $P11$ are about 27% greater than those of $P8$, while $P11$ is about 43% more permeable than $P8$. This, in spite of the fact that the effective sizes of the two samples, in both the foregoing cases are the same.

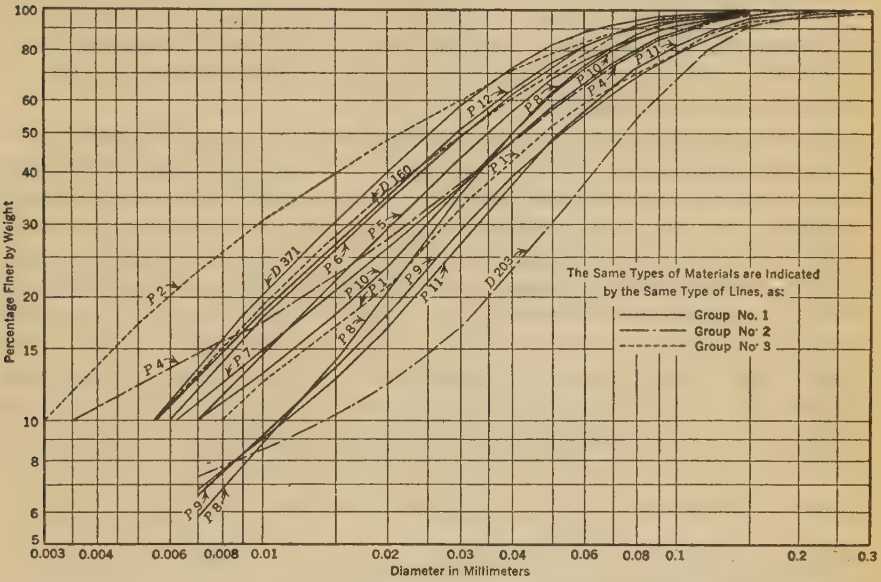

Fig. 16.—Gradation of Samples Tested for Determination of Relation Between Coefficient of Permeability and Percentage of Voids, as Shown in Fig. 15.

Effective Size

Many claim that effective size is an arbitrary term, stating that it may suffice for filter sand where the gradation is more or less uniform and doubt its application to a core material. It is true that without the uniformity coefficient the effective size of a material will give no idea in regard to its gradation. A great many curves can have the same effective size with enormous difference in the gradation of the materials. It should be remembered, however, that the minimum and maximum 60% sizes of the core materials (Fig. 8) are about 0.013 mm. and 0.11 mm., respectively, and that their average value is about 0.035 mm. The effective size term, when applied to a core material, therefore, gives a fair notion of the gradation of that material, especially when the term definitely fixes in mind the maximum size of the 10% fines in the total core.

Mr. Hazen's formula[16] for filter sands is:

$$v = c\,d^2 \frac{H}{l_p} \left(\frac{t + 10}{60} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

It is taken from Darcy's law as expressed by Equation (19), in which, v is the velocity of water, in meters per day; c, a coefficient; d, the effective size, in millimeters; H, the head causing the flow; l_p, the depth of material (filter sand in Hazen's formula); t, the temperature, in degrees Fahrenheit; and K, the coefficient of permeability.

For $t = 50°$ Fahr., or 10° cent. (which is the normal temperature for ground-water) Hazen's $c\,d^2$ becomes equal to Darcy's K. Numerous tests were run to determine the coefficient of permeability, K, for the core material of Cobble Mountain Dam, and, at the same time, to find out whether $c\,d^2$ would be applicable to flows through the extremely fine core materials. The effective sizes of these materials subject to experiments varied from 0.003 mm. to 0.012 mm., and it was discovered that at 45% voids the value of c remained reasonably constant, with a mean average of about 150. The conclusion was reached that Hazen's factor, $c\,d^2$, can be applied approximately for seepage through these fine core materials with $c = 150$. It should be remembered that in using $K = c\,d^2 = 150\,d^2$, K is the coefficient of permeability for velocity, in meters per day, for $t = 50°$ Fahr., and at 45% voids. For any other temperature, the factor, $\frac{t + 10}{60}$, of Equation (22) should be applied and for different percentages of voids Equation (21) can be applied; or perhaps it can be better expressed by:

$$K = 150\,d^2 \left(\frac{V}{45} \right)^6 \left(\frac{t + 10}{60} \right) \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which, K is the coefficient of permeability, in meters per day; d, effective size, in millimeters; V, percentage of voids; and t, temperature, in degrees Fahrenheit.

The value of c may vary considerably from 150, due to variations in the character and gradation of different core materials. For a given locality, however, where the materials are of a similar character and grading, c can be evaluated and used with reasonable accuracy.

It is better, of course, to conduct tests to measure directly the coefficient of permeability of the core material of a dam under construction, in order to calculate, more or less accurately, the probable seepage through the dam, but Equation (23) is a handy tool for computing at least approximately, the probable seepage through the dam before its construction. This might result in very effective changes in the design of the contemplated structure, or in locating other than the anticipated borrow-pits to be used for the construction.

---

[16] Annual Rept., Massachusetts State Board of Health, 1892, p. 539.

The significance of effective size is appreciated and its importance is realized due to the fact that the seepage, all other factors influencing it remaining the same, varies as the square of the effective size. Thus, a computed seepage through a dam in which the material has an effective size of 0.008 mm. will be increased nine times if the effective size is changed to 0.024 mm.

It is hoped that in the future, with more comprehensive investigations, a factor may be obtained for Equation (23) to take into consideration the effect of the slope of the gradation curve. (See Characteristic (3) under "Percolation and Percentage of Voids.")

Effective Size Estimated by Observation

It is surprising to know how easily an inspector at the dam can be trained to judge the approximate effective size of the core material by visual examination and touch. The method of comparing the material from the dam with a sample of similar material that has been tested, is used to train the inspector, and to maintain a constant field check on the work. A series of samples having effective sizes from 0.002 to 0.02 mm. were kept in the field for this purpose.

It was discovered that a core material with an effective size of about 0.002 mm., when rubbed between the fingers, felt like graphite; it was greasy like butter. An experienced inspector can tell the character of a core material in regard to its fineness by observing the flow while it is going over the beach. These observations may not apply directly to other dams, but similar observations may be found useful.

Consolidation of the Core of Cobble Mountain Dam

An attempt has been made to estimate roughly the time necessary for an approximate ultimate consolidation of the core at various heights of the Cobble Mountain Dam. By "approximate consolidation" for various heights of the dam is meant the state of consolidation that the material at any height will attain due to the pressure or weight of the structure itself above that point.

In the laboratory, numerous samples of core material were tested in the standard compression apparatus and corresponding consolidation curves were obtained. For a given material, these curves showed the ultimate percentage of voids of the material under a given load. The application of pressure was made in increments from a very small load up to 200 lb. per sq. in.

It was discovered that the ultimate percentage of voids was affected by the arrangement of the particles (the percentage of voids) at the beginning of the tests and by the effective size of the material. The lower the percentage of voids at the beginning of a test, the lower will be the final percentage of voids. With materials of similar gradation, the larger the effective size, the lower will be the percentage of voids throughout the test.

The average of the laboratory results for local core material with an effective size of 0.008 mm., can be expressed by the equation:

$$100 - V = 49.3\,L^{0.0428} \quad \dots\dots\dots\dots\dots\dots\dots (24)$$

in which, V is the final percentage of voids (expressed in whole numbers, thus, $45\% = 45$ and not 0.45); and L is the pressure, in pounds per square inch, causing ultimate consolidation to $V\%$ voids.

It is questionable whether the consolidation formula obtained in the laboratory will apply to the actual consolidation of the same material in the construction of the dam because of the following reasons:

1.—The applications of the loads in the laboratory and in the dam are different.

2.—The initial percentage of voids or the arrangement of the particles in the testing machine and in the dam is not the same.

3.—The sample for the test in the standard compression machine is very small. It was found that there is a great difference in the time necessary for the ultimate consolidation during a given period under a given loading.

4.—There is a great difference between the inside polished surface of the standard compression unit of the apparatus and the rough surfaces of the abutments and the beaches in the dam.

5.—The time interval for a given load is different.

6.—The drainage facilities are not the same.

7.—There is the question of the load per square inch at any one given depth in the dam, due to the uncertainty of the behavior of the core material in coming to a state of structural equilibrium, or in the rate of consolidation taking place in the upper part of the dam above that particular point. As the percentage of voids in the core decreases, the weight of the core material per cubic foot increases, thus causing a higher pressure per unit area at any depth of the dam.

The consolidation data obtained for Birch Meadow borrow materials may not necessarily apply to other borrow materials in the dam. The results and the formula obtained, should be used with discretion. The application of the formula may not be entirely correct with respect to the actual conditions in the dam; but at present it is the best available information, and, undoubtedly, it is a tool that can be utilized to compute approximately the time of consolidation at various depths.

At the completion of the dam, if the percentage of voids of the core material at any height can be assumed, and the final percentage of voids ascertained from the consolidation formula at that height, the quantity of water to go through a vertical area at the same elevation in the dam can be calculated. The width of the core at any height will determine the path of percolation of the water to be squeezed out at that height; hence, the total quantity of water that will have to drain away can also be determined. Using a certain average velocity of the water, the time necessary for it to drain away can be computed.

It is evident that, in addition to the uncertainties to the application of the consolidation formula, in order to solve the problem, other assumptions are being made, which perhaps are not exactly right.

For example, let B equal the volume of water, in cubic meters, to drain from the core material with a given percentage of voids until it attains the final percentage of voids under a given load; Q, the discharge, in cubic meters per day; v, the average velocity, in meters per day, for V and V'; A, the vertical area, in square meters, perpendicular to direction of flow; T, the number of days; H, the height, in meters, or in feet, below the top of the dam; D, the width of core, in meters, or in feet, at H distance below the top of the dam; V, the initial percentage of voids of core material; V', the final percentage of voids of core material; and d, the effective size of core material, in millimeters.

Assume that horizontal and longitudinal drainage of the water occurs in the core material during consolidation. (This is not exactly the case, as there may always be vertical and diagonal drainage.) Assume, also, that the reservoir is full and that the water in the core material during consolidation cannot flow up stream and that it will drain the full width of the core horizontally down stream. Then, $B = QT = AvT$, or,

$$T = \frac{B}{Av} \qquad \text{(25)}$$

The volume of water, B, to be drained within a section of the core during the change of percentage of voids from V to V' is equal to the original minus the final water content of the section.

With a percentage of voids of V, there are $\frac{V}{100} DA$ units of water and $\frac{100-V}{100} DA$ units of solid material. When the percentage of voids becomes V', there are $\frac{V'}{100} DA'$ units of water and $\frac{100-V'}{100} DA'$ units of material (in which, A' is the reduced area due to consolidation); but, $\frac{100-V}{100} DA = \frac{100-V'}{100} DA'$, or,

$$A' = A \, \frac{100 - V}{100 - V'} \qquad \text{(26)}$$

and $B = \frac{V}{100} DA - \frac{V'}{100} DA'$, or,

$$B = \frac{D}{100} (AV - A'V') \qquad \text{(27)}$$

Substituting the value of A' from Equation (26) in Equation (27),

$$B = DA \, \frac{V - V'}{100 - V'} \qquad \text{(28)}$$

The rate of consolidation of the material under a given constant load, shortly after the application of the load, becomes almost uniform. It is reasonable to assume, therefore, that the average velocity of water drained during the consolidation from a percentage of voids of V to V' will be about the velocity at $\frac{V + V'}{2}$; then, from Equations (22) and (23) and for $A = 1$ sq. m.,

$$v = 150\, d^2 \, \frac{H}{D} \left(\frac{V + V'}{2 \times 45} \right)^6 \qquad \text{(29)}$$

Substituting Equations (28) and (29) (for $A = 1$) in Equation (25) and reducing the meter units to feet,

$$T = \frac{D^2 (V - V')}{492\, d^2 H (100 - V') \left(\frac{V + V'}{90}\right)^6} \quad \ldots\ldots\ldots\ldots\ldots (30)$$

It is evident from the time formula, Equation (30), that the lower the point under consideration in the Cobble Mountain Dam the longer it will take for final consolidation. Then the bottom of the dam only should be considered, say, Elevation 730.

Assuming that the average percentage of voids of the core material of the entire dam at its completion is 47.5 and that the specific gravity of the solid material is 2.72, the combined weight of water and material per cubic foot is 119 lb., corresponding to a specific gravity of 1.9, or 0.825-lb. pressure per sq. in. for each foot of head. The elevation at the top of the dam is 973; then at Elevation 730 the load will be $0.825 \times 243 =$ about 200 lb. per sq. in. The ultimate percentage of voids of the core material subject to a 200-lb. load per sq. in., is 38.15 according to Equation (24). Hence, V equals 45% at the bottom of the dam; V', 38.15%; D, 170; d, 0.008 mm.; and H, 222 (flow-line elevation = 952). Inserting the foregoing in Equation (30), $T = 735$ days.

Considering that—(*a*) there is always vertical drainage during construction; (*b*) after construction the drainage is not horizontal only; (*c*) it will take about a year for the reservoir to fill; and (*d*) during this period, if not also afterward, the drainage will take place horizontally both up stream and down stream, thus cutting in half the length of the path of percolation—it may be permissible to reduce the period of 735 days from 25 to 50%; in other words, the time necessary for the consolidation of the Cobble Mountain core may be from about 1 year to 18 months.

It should be remembered that Equation (24) is obtained with samples of an effective size of 0.008 mm. from the middle of the core. Naturally, the average effective size of the core is more than 0.008 mm., in which case the time necessary for the ultimate consolidation would be less.

As noted in Equation (30), T, number of days for consolidation, varies inversely as the square of the effective size. The average effective size for the entire core is 0.009 mm. Therefore, with an effective size of 0.009 mm. the number of days for consolidation will be, $T = 735 \left(\frac{0.008}{0.009}\right)^2 = 580$ days. This is practically within the range of the aforementioned estimated time of 1 year to 18 months.

SEEPAGE FORMULA FOR HYDRAULIC-FILL DAMS

Now that an average approximate value has been ascertained for the coefficient of permeability of the core material, the problem is to apply this information so as to be able to calculate the seepage through a hydraulic-fill dam. As far as the writer knows, there is no such general formula giving the seepage through any hydraulic-fill dam; and the derivation of such a general formula is given in the following pages.

FIG. 18.—CORE SECTION.

It is proposed to use Darcy's law (Equation (19)), in deriving such a general formula. The controlling factor in the seepage through any hydraulic-fill dam, with a known or assumed coefficient of permeability of its core material, will be the section of the core of that dam, provided the core has assumed a sufficient state of consolidation to make it stable. The simplest way that Darcy's formula can be applied is to assume a horizontal flow for the seepage, although it is a fact that such is not exactly the case, at least for the upper section of the core. The diagonal flow of the seepage through the core in the upper part of the dam may result in the reduction of the core area affecting the percolation. On the other hand, there may be some clogging of the upper surface of the core resulting in decrease of percolation. However, the general seepage formula in this paper will be accurate enough for all practical purposes in estimating approximately the loss of water by seepage through the core. Fig. 17 shows the maximum cross-section of Cobble Mountain Dam.

In Fig. 18, let D = width of core = path of percolation, l_p, at H-distance below the flow line; D_1 equal the width of core = l_p, at flow-line elevation; D_2, width of core = l_p, at bottom of the dam; l, length of dam at H-distance below the flow line; l_1, length of dam at flow-line elevation; l_2, length of dam at bottom; and, H_2, height of dam to flow-line elevation.

In the hypothetical case of a rectangular core section (see Fig. 18(a): $D = l_p = D_1 = D_2$ and $l = \frac{l_1 H_2 - (l_1 - l_2) H}{H_2}$. From Fig. 18($a$), $d A = l\, d H$, and the derivative of Equation (19) is,

$$d Q = K \frac{H}{D} d A = K \frac{H}{D} l\, d H \qquad (31)$$

Substituting values of D and l in Equation (31),

$$d Q = K \frac{H}{D_2}\left[\frac{l_1 H_2 - (l_1 - l_2) H}{H_2}\right] d H$$

or,

$$Q = K \frac{l_1}{D_2} \int H\, d H - K \frac{(l_1 - l_2)}{D_2 H_2} \int H^2\, d H + k$$

Integrating between the limits, $H = H_2$ and $H = 0$, and simplifying,

$$Q = K \frac{H_2^2}{6\, D_2} (l_1 + 2\, l_2) \qquad (32)$$

Equation (32) expresses the seepage through a hypothetical, rectangular core section (Fig. 18(a)). Substituting $l_1 = l_2 = l$, then,

$$Q = \frac{K}{2\, D_2}\, l\, H_2^2 \qquad (32a)$$

Equation (32a) expresses the seepage for a length, l. In the general case of a trapezoidal core section, for any hydraulic-fill dam (Fig. 18 (b)),

$$D = \frac{D_1 H_2 + (D_2 - D_1) H}{H_2}$$

and,

$$l = \frac{l_1 H_2 - (l_1 - l_2) H}{H_2}$$

As in the hypothetical case, $d\,Q = K \frac{H}{D} l\,d\,H$. Substituting values of D and l, as before,

$$d\,Q = \frac{K\,H\,H_2\,[l_1 H_2 - (l_1 - l_2)\,H]}{[D_1 H_2 + (D_2 - D_1)\,H]\,H_2}\,d\,H$$

or,

$$Q = K\,l_1\,H_2 \int \frac{H\,d\,H}{D_1 H_2 + (D_2 - D_1)\,H} - K\,(l_1 - l_2) \int \frac{H^2\,d\,H}{D_1 H_2 + (D_2 - D_1)\,H} + k \quad \ldots\ldots\ldots (33)$$

Integrating Equation (33) between the limits, $H = H_2$ and $H = 0$, and simplifying,

$$Q = \frac{K\,H^2_2}{(D_2 - D_1)^3} \left\{ l_1 \left[\tfrac{1}{2}\,(D^2_2 - D^2_1) - D_2\,D_1 \log_e \frac{D_2}{D_1} \right] + l_2 \left[\frac{D^2_2}{2} - 2\,D_2\,D_1 + \frac{3}{2}\,D^2_1 + D^2_1 \log_e \frac{D_2}{D_1} \right] \right\} \ldots\ldots\ldots\ldots (34)$$

Equation (34) is the general seepage formula for any dam having more or less uniform slopes for the core section and the dam site. In case of any appreciable change in the slopes of the dam site, the equation can be applied in steps for different sections or heights of the dam, and their sum will give the total seepage. When $l_1 = l_2 = l$, Equation (34) becomes:

$$Q = \frac{K\,H^2_2\,l}{(D_2 - D_1)^2} \left\{ D_2 - D_1 - D_1 \log_e \frac{D_2}{D_1} \right\} \ldots\ldots\ldots\ldots (35)$$

which is the seepage for a trapezoidal core section of a dam for a length, l. Substituting $D_1 = 0$ in Equation (34),

$$Q = \frac{K\,H^2_2}{2\,D_2}\,(l_1 + l_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

which is the seepage for a triangular core section of a dam with different length for top and bottom. When $D_1 = 0$ in Equation (35),

$$Q = \frac{K\,H^2_2}{D_2}\,l \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

which is the seepage for a triangular core section of a dam for a length, l. When D_1 approaches D_2, Equation (34) approaches Equation (32), as its limiting value.

The difficulty with Equation (34) is that it is too long and contains logarithmic terms which make it rather cumbersome for rapid calculations. An investigation of these several seepage formulas for different geometric core sections will show that there is a relation between the seepage quantities and the areas of different core sections. This relation can be expressed as follows; let $Q_1 =$ seepage according to Equation (34); $Q_2 =$ seepage according to Equation (32); $A_1 = \frac{H_2}{2}(D_1 + D_2) =$ area of a trapezoidal core section, Equation (34); and $A_2 = D_2 H_2 =$ area of a rectangular core section, Equation (32). Then,

$$\frac{Q_1}{Q_2} = \frac{A_1}{A_2} X \qquad (38)$$

in which, X is a factor depending on ratios of $\frac{D_1}{D_2}$ and $\frac{l_2}{l_1}$.

Substituting values of Q_1, Q_2, A_1, and A_2, and solving for X,

$$X = \frac{12\, D^2_2\, l_1 \left[\frac{1}{2}(D^2_2 - D^2_1) - D_2 D_1 \log_e \frac{D_2}{D_1}\right]}{(D_2 + D_1)(D_2 - D_1)^3 (l_1 + 2\, l_2)} + \frac{12\, D^2_2\, l_2 \left[\frac{D^2_2}{2} - 2\, D_2 D_1 + \frac{3}{2} D^2_1 + D^2_1 \log_e \frac{D_2}{D_1}\right]}{(D_2 + D_1)(D_2 - D_1)^3 (l_1 + 2\, l_2)} \qquad (39)$$

Substituting values of Q_2, A_1, and A_2, in Equation (38) and solving for Q_1,

$$Q_1 = \frac{X K H^2_2}{12\, D^2_2}(l_1 + 2\, l_2)(D_1 + D_2) \qquad (40)$$

but Q_1 is the seepage in Equation (34); therefore, the general equation for any trapezoidal core section for a hydraulic-fill dam becomes,

$$Q = X K H^2_2 (l_1 + 2\, l_2) \frac{D_1 + D_2}{12\, D^2_2} \qquad (41)$$

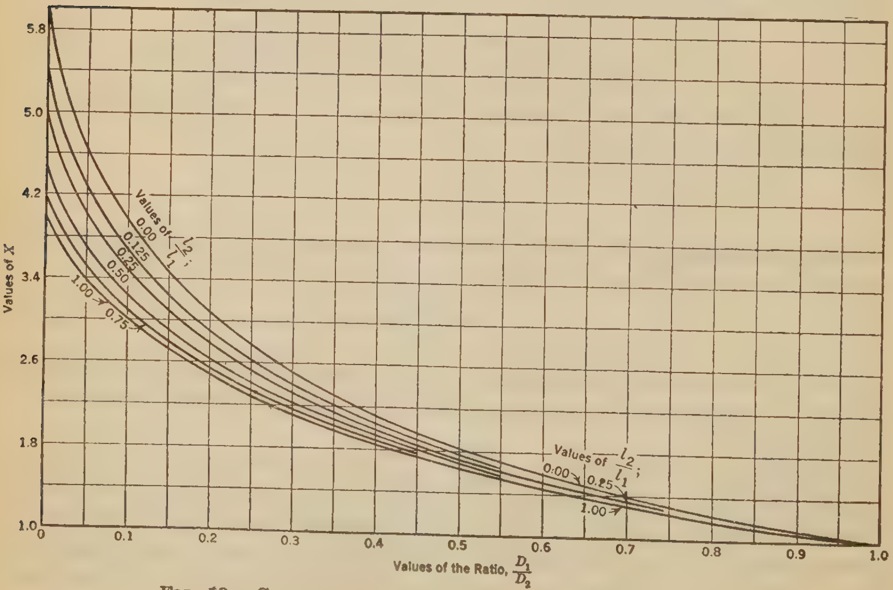

FIG. 19.—CURVES FOR SOLUTION OF EQUATION (39).

The values of X corresponding to different ratios of $\frac{D_1}{D_2}$ and $\frac{l_2}{l_1}$, can be picked from the curves of Fig. 19. It will be noted that X has a minimum value of 1 and a maximum value of 6.

Assuming that K is expressed in meters per day at 10° cent., and at 45% voids, the general seepage formula for any hydraulic-fill dam—at any percentage of voids (within working ranges), for any temperature, in gallons per day—may be expressed approximately by,

$$Q = 24.54\ X\ K\ H^2_2\ (l_1 + 2\ l_2) \left(\frac{D_1 + D_2}{12\ D^2_2}\right) \left(\frac{V}{45}\right)^5 \left(\frac{t + 10}{60}\right) \ldots\ldots (42)$$

and substituting 150 d^2 for K in Equation (42),

$$Q = 300\ X\ d^2\ H^2_2\ (l_1 + 2\ l_2) \left(\frac{D_1 + D_2}{D^2_2}\right) \left(\frac{V}{45}\right)^5 \left(\frac{t + 10}{60}\right) \ldots\ldots (43)$$

in which, Q is the quantity of flow, in gallons per day; K, the coefficient of permeability, in meters per day, at 10° cent. and at 45% voids; V, the percentage of voids varying from 30% to 60%; and the other factors are as previously defined.

ACKNOWLEDGMENT

Credit is given throughout the paper for the data used from other sources. The writer is indebted to: The late Allen Hazen, M. Am. Soc. C. E., who, before his death, read the manuscript (which then consisted of about the first half of this paper), and made useful suggestions; E. E. Lochridge, M. Am. Soc. C. E., Chief Engineer of the Board of Water Commissioners, Springfield, Mass., who, realizing the importance of such a laboratory for the construction of the Cobble Mountain Dam, allowed the necessary funds for the purpose and kept up useful interest in the work with criticisms and suggestions; the Engineering Staff at Cobble Mountain Reservoir, especially Mr. R. H. Alberti and Nathaniel Clapp, Jun. Am. Soc. C. E., who took a keen interest in the subject-matter and not only did the routine work, but also rendered valuable assistance in the preparation of the paper.

DISCUSSION

Charles H. Paul,[17] M. Am. Soc. C. E. (by letter).—The author is to be commended both for the purpose of his paper, and for the careful detail in which the proposed tests are described. Engineers interested in hydraulic-fill dam construction will find this paper valuable for study and for reference.

As Consulting Engineer during the last fifteen months of hydraulic-fill construction, the writer made regular visits to the Cobble Mountain Dam and had the opportunity to observe the ingenuity and competence of the engineers in developing practical methods of making tests for control and records of hydraulic-fill operations.

While the hydraulic-fill method of dam construction has been in use for many years, it is true that systematic study of the details of design and construction peculiar to this type has been made only within the last decade or two. Even to the present time there are few accepted standards available for investigating or testing materials, or for determining results as the work proceeds.

It is an accepted fact that there is a wide range of materials suitable for hydraulic-fill construction, as to shoulder material as well as core material. This may be seen by a study of the descriptions of the many successful dams of that type that are now (1932) in service. Progress in standardizing testing methods unquestionably will lead to more careful consideration of the requirements of design to fit the materials available. Therefore, it is quite probable that this paper may lead to an indirect result fully as important as its main purpose.

Borrow-pit sampling begins with methods generally accepted for the investigation of materials for any earth dam, but must be carried much further. Core material available is limited approximately to the quantity passing the 200-mesh sieve. An excess over apparent requirements is necessary, as some of the fines will be trapped in the beaches, and it helps core control to be able to waste some fines.[18] After the amount available has been determined and found to be sufficient, various core tests should be made for specific gravity, gradation, percentage of voids, permeability, etc., methods for which are outlined in the paper. The gradation of the coarse material in the borrow-pit should also be investigated (this may be done by screens and sieves), as the stability and free drainage of the shoulder material is fully as important as the impermeability and satisfactory rate of consolidation of the core.

The author describes the usual method of determining moisture content and percentage of voids in core and beach materials. This is a simple procedure and gives satisfactory results. His Fig. 2 shows the percentage of voids decreasing with the distance from the center line of the core. At first, the relatively high percentage of voids in the core may appear to be illogical, but that seems to be characteristic of such materials. It should be remembered that the voids in the core are microscopic, and even if they comprise a large percentage of the mass, their extremely small size renders the mass practically impervious. By reference to another section of this paper (see under "Effective Size"), it may be inferred that the rate of permeability decreases as the square root of the size of voids. Several samples of cores from the Miami Conservancy dams averaged 40% voids (weight, 125 lb. per cu. ft.; specific gravity of solids, 2.67), but the coefficient of permeability through that material was found by Glennon Gilboy, Jun. Am. Soc. C. E., to be only 0.0144 cm. per day. These void determinations on the Miami Conservancy cores were obtained from samples taken from the cores after seven years' consolidation, and, therefore, tend to confirm the results obtained by the author at Cobble Mountain. These results are further confirmed by records at many other hydraulic-fill dams.

---

[17] Cons. Engr., Dayton, Ohio.

[18] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), pp. 1181, 1188, and 1236.

In making and recording void determinations, care should be taken to make clear whether the amount of moisture is determined and expressed as a percentage of the entire weight (water plus solids), or of the solids alone. For example, in a sample of saturated core weighing 125 lb. per cu. ft., a water content of 25% of the mass by weight would mean 50% voids, while 25% of the dry or solid matter would mean 40% voids. There has been some confusion in the past because of lack of care in expressing or interpreting the results of moisture content determinations. The writer prefers the practice of expressing moisture content in percentage of the entire weight. That is the meaning of w in the author's Equation (1).

The writer has expressed the opinion repeatedly that rod penetration tests as ordinarily made from a boat give only indefinite results.[19] They are of some value in determining in a general way the rate of consolidation, and in detecting the presence of tongues of sand or gravel that may have worked out into the core. The author has described a more refined method of making these tests, which seems to give fairly reliable results.

Several methods of determining grain sizes and gradation of core materials have been described by Mr. Hatch, including the hydrometer method. The writer agrees with the conclusion that this method has many advantages, such as speed, low cost, convenience, and reasonable accuracy. The procedure is outlined in detail, step by step. It is hoped that this hydrometer method may be adopted for general use in the investigation of borrow-pit materials and in hydraulic core tests.

With reference to suitable sizes of core materials, it may be said in general that while the presence of impalpably fine particles makes for less permeability, it tends to increase the difficulties of construction. Character of borrow-pit materials available, study of core gradations and construction records at other hydraulic fills, and good judgment must contribute to the decision in each case as to whether the hydraulic-fill type is practical and economical.

---

[19] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1800, and Vol. LXXXV (1922), p. 1193.

In a paper describing core studies at the Miami Conservancy Dams,[20] the writer gave analyses of representative samples of the cores of those five dams, all of which averaged much finer in sizes of particles than the Cobble Mountain core. The Miami core material averaged about 0.002 mm. for effective size and about 15 for uniformity coefficient, using those terms for want of something better to indicate fineness and gradation for purposes of comparison. Observation and tests show those cores to be highly impervious, and their rate of consolidation was fast enough for all practical purposes. Samples of the core taken after consolidation averaged 40% voids and weighed 125 lb. per cu. ft. The average specific gravity of the particles was 2.67, and that of the mass, 2.00. The material of the Cobble Mountain core had an effective size of about 0.009 mm. and a uniformity coefficient of about 8. Although much coarser than that of the Miami Conservancy, this material also gave satisfactory results as regards water-tightness, stability, and rate of consolidation. At some dams where cores were somewhat finer than those of the Miami Conservancy District, more or less trouble has occurred during construction, and not many cores are much coarser than at Cobble Mountain; but between the wide limits indicated by those two, it is reasonable to assume that core materials will be satisfactory unless preliminary tests point to the contrary. The author has wisely called attention to the fact that frequent gradation analyses are necessary to obtain a representative gradation curve at any dam. The hydrometer method, as described, makes this comparatively easy and practicable. His method of plotting these curves is believed to be logical, and may well be standardized.

The author's conclusions regarding the coefficient of friction of beach and shoulder materials (see text following Equation (18)) seem logical, and may be put into practical application in the design of the shoulder sections of hydraulic-fill dams, although in many cases other considerations, such as angle of repose, may require a volume of shoulder material that will eliminate the necessity of more than a passing consideration of the coefficient of friction.

Percolation tests are difficult to make and to interpret for practical application. Nevertheless, such tests are extremely desirable in the investigation of earth dam materials and the writer knows of no more practical apparatus for such determinations than the one described as the "Large Percolator." While it may be difficult to make a direct application of the results of such tests, they certainly furnish valuable information for comparisons of different materials available, or for possible variations in gradations. These tests, either on the job or at some available laboratory, are considered to be well worth while. As would be expected, a conclusion from the author's investigation is that both finer grain sizes (which means smaller void sizes), and lower percentages of voids, have a strong influence in reducing permeability.

As to rate and manner of core consolidation, the experience with the Miami Conservancy District cores heretofore described, showed that they reached a condition very close to final consolidation in not more than twelve months after placing. The rate of construction progress has a marked effect on this, of course, since the faster the load is applied the more rapid is the consolidation process. In this connection (referring to the discussion involving Equations (25) to (30)), the writer is convinced that considerable of the core drainage takes place vertically.[21] The writer believes that this vertical drainage will have even more effect than is suggested by the author.

---

[20] "Core Studies in the Hydraulic-Fill Dams of the Miami Conservancy District," by Charles H. Paul, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), pp. 1181–1236.

Notwithstanding the difficulties in applying results of percolation tests to actual conditions in a dam, nevertheless such tests may often suggest limits that will be safe to apply to the dam itself. In such cases the author's seepage formula (Equation (43)) is set up in comparatively simple and convenient form for use. It should be realized also that this formula is applicable to the seepage-resisting materials in any type of earth dam, and not to hydraulic cores only.

It is the writer's belief that a well-built hydraulic core, composed of materials within the limits of fineness being discussed in this paper, will scarcely permit enough seepage to cause any concern. From the nature of their construction, hydraulic-fill dams are particularly adapted to resist seepage through the core itself, and to distribute such seepage harmlessly and effectively through the beach and shoulder materials on the down-stream side. Assuming that the core is homogeneous, what little seepage may occur will be taken care of automatically. One thing to be watched carefully is the preservation of uniformity in the core during construction, and the prevention of tongues or layers of sand or gravel that will provide a path for free seepage. Seepage formulas must necessarily assume the absence of any such conditions as that.

In many cases, also, it will be found that the dam itself is more watertight than the abutments against which it rests. Seepage dangers should be investigated through abutments and foundations of earth dams, as well as through the dams themselves, as otherwise these abutments or foundations may be the source of the greater danger.

JOEL D. JUSTIN,[22] M. AM. SOC. C. E. (by letter).—The author has performed a valuable service to the profession in making available the laboratory control methods utilized on the Cobble Mountain Hydraulic-Fill Dam. It is to be feared, however, that many engineers not previously acquainted with these methods will gain the impression, on reading Mr. Hatch's paper, that the laboratory control there practiced was unduly elaborate and expensive, and, therefore, not applicable to work which they might be contemplating.

The writer knows that such an impression would be erroneous. The cost of the laboratory equipment utilized was not great, and the total cost of laboratory control was only a small part of the cost of engineering supervision and only an insignificent percentage of the cost of the structure. Accordingly, the writer believes that it will help to promote the use of laboratory control methods similar to those utilized at Cobble Mountain, if Mr. Hatch will give some data on the cost of the laboratory, the number of men employed in this branch of the work, and the total cost of laboratory control for the job, together with the cost per cubic yard of material in the dam. Such data would also help engineers responsible for the design and construction of earth dams in persuading their principals that it is worth while and not unduly expensive to have a thorough laboratory control on such work.

---

[21] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), pp. 1194, 1199 (Fig. 11), and 1201.

[22] Cons. Engr., Philadelphia, Pa.

The magnitude, character of materials available, and type of dam used, should govern the degree of elaborateness adopted for laboratory control. With the advantage of the pioneer work in this line done by the late Allen Hazen, M. Am. Soc. C. E., and Mr. Hatch at Cobble Mountain Dam, and by a few others elsewhere, the necessary cost of laboratory control for most earth dams may be quite insignificant. Thus, at the Bee Tree Dam,[23] a hydraulic-fill dam, in North Carolina (177 ft. high), Charles E. Waddell, M. Am. Soc. C. E., utilized a sufficiently precise method of laboratory control for the existing conditions at a cost for laboratory equipment of less than $750, and one laboratory man and an assistant did practically all the work required.

In his Fig. 2, the author shows for a particular case, the percentage of voids in the core and in the beaches at various distances from the center line. The percentage of voids in the core is shown to exceed 50% slightly, the voids decreasing with the distance from the center line until at about 240 ft. the voids in the beaches are 25% on one side and 33% on the other side of the center line. In spite of this, the beach, because of the tremendously greater size of pores, was undoubtedly much more pervious than the core. The author does not state the depth below the surface of core pool or silt line at which the core samples were taken; nor does he state how long the core material, which had more than 50% of voids, had been in place.

One of the most compelling reasons for having a thorough laboratory control system in hydraulic-fill earth-dam construction is to obtain data that will enable one to control the stability of the core during the critical period while construction is in progress. The author gives a formula (Equation (24)) for determining the ultimate percentage of voids in the local core material at any depth, and another formula (Equation (30)) for determining the time it takes to secure this ultimate percentage of voids. He does not, however, give the percentage of voids in the core, which it is necessary to secure in order to have a stable core, nor the length of time, height, or pressure of material above, required to obtain this stable core. By a stable core is meant a condition of the core such that it is practically self-sustaining, and, therefore, does not exert material pressure against the retaining beaches or toes. The writer believes that the degree of stability of the core at different elevations during the progress of construction is one of the most important things that the engineer charged with the responsibility for the design and construction of a hydraulic-fill dam wants to know.

At the Calaveras Dam investigation, Mr. Hazen found that core material having 50% of voids exerted practically full hydrostatic pressure, but that core material having 40% of voids was sufficiently stable. The material in the Cobble Mountain core was much coarser than that at Calaveras, and it would be interesting to know at what percentage of voids the material became sufficiently stable.

---

[23] "Earth Dam Projects," p. 94, John Wiley & Sons, Inc., N. Y., 1932.

Under "Seepage Formula for Hydraulic-Fill Dams," Mr. Hatch states that, so far as he knows, "there is no such general formula giving the seepage through any hydraulic-fill dam; * * *," and then proceeds to develop a formula for seepage through the core of such a dam. He is not entirely correct in this statement. A formula that may be used for this purpose was developed by Mr. Hazen, and is given by Mr. Hatch as Equation (22). The writer has previously given formulas for seepage through earth dams and also for seepage through the foundation soil.[24] These formulas are merely adaptations of the well-known Slichter formula to the conditions existing in earth dams. All these formulas, as well as that of the author, are based on the Darcy formula first presented in 1857 and given by Mr. Hatch as Equation (19).

The thoroughness with which laboratory control methods were developed and applied at Cobble Mountain have not been equalled elsewhere, as far as the writer is aware, and the detailed discussion of these methods given by Mr. Hatch will be extremely useful to all engineers engaged in the design and construction of earth dams.

JEPTHA A. WADE,[25] M. AM. SOC. C. E. (by letter).—The soil hydrometer described by Mr. Hatch is of interest where approximate results will serve and the elutriation method requiring more elaborate laboratory equipment is not justified. Apparently, judged by empirical standards, the results are consistent and close enough for ordinary purposes. By this method a good check can be kept on the materials entering a dam. It may also be used in determining whether the available dam material is suitable for hydraulic placement, or whether a rolled embankment is to be recommended due to excessively small grain size. It has been used, on work under the writer's charge, in analyzing samples from core borings in soft foundations to determine the probable seepage underneath an earth dam. Other applications will doubtless appear. Due to its comparative simplicity, both of apparatus and manipulation, it is undoubtedly a useful tool, and Mr. Hatch is to be commended for having developed the method for its use.

It is somewhat to be regretted that the paper does not go more fully into the underlying theory, with a frank statement of the factors that have been neglected and a determination or estimate of their limiting values. As it stands, the discussion is not entirely clear, considerable reliance being placed on the fact that the results agree fairly well with those obtained by elutriation.

The statement (under the heading, "The Hydrometer") of what is happening in the sample under test, is somewhat confusing—in fact, not strictly true. Assuming that the graduate contains a uniform mixture from top to bottom and that settlement takes place in accordance with Stokes' law, there will be particles of all sizes at all levels when the test is started. All these particles immediately begin to settle at rates dependent on their respective diameters. Each horizontal section will gain from above the same number of particles of a given diameter as it loses to the section beneath, the only exception being at the top where none can be supplied and the number of particles in suspension, therefore, becomes smaller. Particles originally near the bottom begin to come to rest on the bottom of the graduate. As time goes on, the available supply of particles of a given size above a given section becomes exhausted and the total grams in suspension per liter at that point is decreased. There are still particles of all the smaller sizes above this point, and of all sizes below this point.

---

[24] "Earth Dam Projects," pp. 139 and 174.

[25] Chf. Engr., California Water Service Co., San Francisco, Calif.

Conditions at the various levels at any time can be determined if the analysis of the material in suspension is known. Assume that this is as given in Table 3 of the paper, or that the graduate contains:

45.58 grams smaller than 0.09 mm in diameter (200-mesh screen)
27.2 grams smaller than 0.0467 mm in diameter
19.7 grams smaller than 0.0345 mm in diameter
11.9 grams smaller than 0.0230 mm in diameter
8.9 grams smaller than 0.0165 mm in diameter
5.9 grams smaller than 0.0097 mm in diameter
4.2 grams smaller than 0.0069 mm in diameter

Suppose these quantities are plotted as abscissas marking the vertical lines between the bands with the separation sizes. Next, apply Stokes' law, determining the distance a particle of each separation size would drop in each of the times for which readings were taken. Plot these distances as ordinates measured down from the top, which represents the surface of the liquid. In 1 min each particle, 0.09 mm in diameter, will have dropped 44.58 cm. There will be no particles as large as this nearer the surface, but at greater depths the number of this size per liter will be uniform and the same as at the beginning. Particles, 0.0467 mm in diameter, will all have traveled 11.94 cm, those 0.0345 mm in diameter, 6.54 cm, etc. If these distances are plotted on the lines representing these sizes and a curve is drawn through the points, the result is a curve above which no particle of the size represented by the abscissa exists at the end of 1 min and below which conditions are the same as they were at the beginning. Since horizontal distances represent grams per liter the abscissas of the curve represent the total grams per liter at the various depths below the surface at the end of 1 min. Similar curves can be drawn for the other time intervals as shown in Fig. 20.

The hydrometer depends on the density of the displaced liquid for its operation. While there may be a question as to suspended solids increasing the density of the liquid it appears that, within certain limits at least, water with material in suspension affects the hydrometer generally as if this were true. While this suggests itself as a subject that might properly be investigated, no such attempt will be made here, the assumption being that the relation is a true one. It now appears that, in the work under discussion, the hydrometer is being used in a very peculiar manner, namely, in a liquid having different densities at different depths, increasing from the top down. What is the resultant effect? The buoyancy exerted on any floating body is equal to the weight of the displaced liquid which must also equal the weight of the floating body. The hydrometer reading indicates a summation of all the buoyant forces acting on the hydrometer; that is, each horizontal section of displaced volume multiplied by its respective density. The reading might be termed the resultant of all these forces.

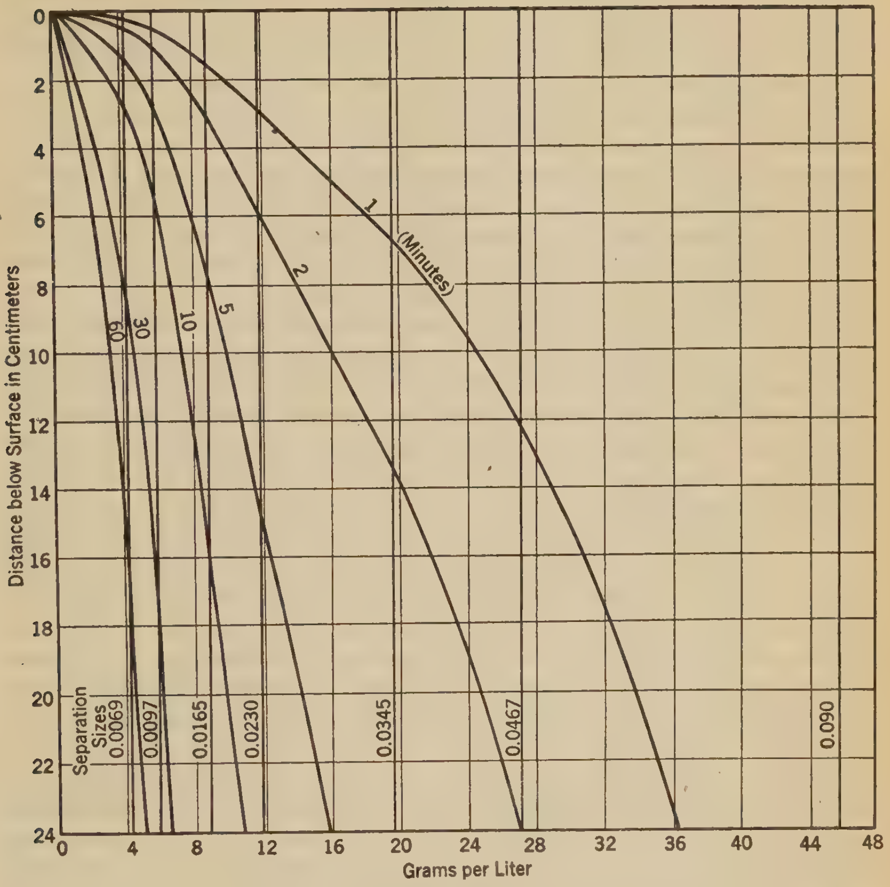

FIG. 20.—GRAMS PER LITER AT DIFFERENT DEPTHS AT TIMES READINGS ARE TAKEN. (ANALYSIS OF MATERIAL AS IN TABLE 3.)

The use of the hydrometer for analysis purposes, therefore, depends on finding the horizontal plane in which the actual grams per liter in suspension, if it was constant throughout the displaced volume, would produce the same effect as is actually obtained. Mr. Hatch assumes that this level is at the center of buoyancy of the hydrometer, but examination of Fig. 20 indicates a slight error in the assumption. Suppose, for the moment, that the hydrometer was cylindrical in form. The center of buoyancy would then be exactly half way between the surface of the liquid and the bottom of the hydrometer.

The density lines will usually be convex upward, as they are in Fig. 20, since any other hypothesis denotes an extraordinary preponderance of the larger sizes. The density at the mid-point will obviously be greater than the mean, and the density equal to the mean will be found at a higher level. Since the center of buoyancy is the center of gravity of the displaced liquid, it is probable that the concentration corresponding to the reading of the instrument will always be found at some higher point. Distances used in Column (5), Table 3, are, therefore, too great, resulting in too great velocities of fall in Column (6) and too large diameters of particles in Column (8).

It would appear impossible to evaluate this error, depending as it does on the analysis, except by "cut-and-try" methods involving a large number of computations which the results actually obtained do not seem to justify. Correcting it would increase the divergence from elutriator results pointed out by Mr. Hatch under the heading "Comparison of Elutriator and Hydrometer Method Results," and it would appear, therefore, that there are other compensating factors which have not been considered.

Another point, also of minor importance, concerns the graduations of the instrument. Dr. Bouyoucos states[25a] "the hydrometer was calibrated on average normal loam soils." Nothing is said about the specific gravity. Between the two specific gravities encountered at Cobble Mountain, there would be a difference in the instrument reading of about 1 gram per liter where the readings are approximately 60 grams per liter and proportionally smaller errors accompany smaller readings. The error here is not likely to be large, but can be evaluated easily by calibrating with material of known specific gravity. Dr. Bouyoucos also states[25a] "in peats and mucks the hydrometer method is not very reliable, first, because these materials are almost impossible to disperse and, second, because they have a smaller specific gravity." While peats and mucks are not classified as suitable dam materials, this raises another question, namely, does the specific gravity change during the process of settlement enough to effect the results? Perfect homogeneity is not to be expected.

The question of dispersing the solids properly is sometimes troublesome. One reagent may work properly with one material and may be an absolute failure with another. It would be helpful if Mr. Hatch would append a list of those that may be tried, since trial seems to be the only way of determining this vital point.

It is not felt that any of the points discussed are of enough importance to put the method in serious doubt. Rather, it is felt that discussion of them is essential to a better understanding which must precede the general adoption of the method and perhaps lead to its improvement. It is to be noted that temperature corrections have been applied in Column (4), Table 3, that are much closer than it is possible to read the hydrometer and that the viscosity is 1.00 for a temperature of 68° F. It would seem possible to control the temperature closely enough so that these corrections might be neglected, without causing important errors. This would simplify operation considerably. It is quite probable that a few check runs with an elutriator on the material from a given location will determine a fairly constant correction by which hydrometer and elutriator results may be brought into close agreement. The errors, with the exception of temperature, evidently have some relation to the analysis. Mr. Hatch very properly points out that the individual hydrometer must be calibrated, and it is believed that, if this is done and an occasional check made in a laboratory equipped for elutriation, the hydrometer may be used with entire confidence.

[25a] "A Comparison of the Hydrometer Method and the Pipette Method for Making Mechanical Analysis of Soils with New Directions," by George John Bouyoucos, *Journal*, Am. Soc. of Agronomy, August, 1930, Vol. 23, No. 4, p. 750.

STANLEY M. DORE,[26] ASSOC. M. AM. SOC. C. E. (by letter).—Engineering supervision of the construction of large dams of the earth embankment type has included first, the inspection and choice of construction materials, and, second, the regulation of the manner of incorporating the materials chosen into the structures. In recent years the soil testing laboratory has taken an important and active part in the study of materials in connection with both these phases of the supervision, and the decisions made before and during construction have been influenced considerably, and justly so, by its findings. Construction of dams, by the hydraulic or the semi-hydraulic methods especially, has been dependent upon and governed by the periodic analyses and tests of the laboratory, in order that the quality of the material in the finished structure may be ascertained. Thus, the findings of the laboratory for any such project constitute data of vital significance and utmost value to those interested in earth embankment design and construction.

The manner in which testing has been conducted on recent large projects has varied considerably, however, the engineers on each devising and inventing their own methods and apparatus to a large extent and interpretating their own data. The result has been that the findings obtained for one project have not been comparable with those for another, and for that reason many significant data have failed to be as valuable as they should to the Engineering Profession. The need for standardization of methods and apparatus is decidedly apparent. The author's appeal for such standardization is to be considered seriously and energetic action, through engineering organizations, toward that end is strongly recommended. Much has been done under the direction of such governmental departments as the U. S. Bureau of Public Roads, the U. S. Bureau of Agricultural Research, and the U. S. Geological Survey, and papers and reports dealing with the subject have been written by Messrs. Hazen, Slichter, King, Stearns, Meinzer, Terzaghi, and others. Many of these works may be of use in the standardization of soil testing, but considerable thought and discussion of the problem are urgently needed at present.

Soils, the most abundant natural construction material, have quite variable structural characteristics—even similar soils in one locality. Adequate standard terms for discussing these variable characteristics are lacking to some extent and definition of them in simple practicable terms might well constitute the first step toward standardization. Even though two materials to be compared have radically different characteristics, the existence of common definitions would permit the description of these differences so clearly that studies of the results of analyses made of them would be productive of useful data. In contrast, the lack of common adequate phraseology and definitions makes comparisons of test results futile as the true differences of the materials compared are not fully understood, simply because at present this deficiency hampers minute and clear descriptions of those differences.

---

[26] Asst. Designing Engr., Met. Dist. Water Supply Comm., Boston, Mass.

The mechanical analysis of a soil sample is probably the most widely used single test of soil characteristics, and attention is directed to the author's recommendation for the careful rating of sieves and for the accurate determination of the finer particles. For the latter he indicates that successful results can be obtained with either the elutriation or hydrometer method, and that the use of both may be advisable. In addition, it seems that considerable might be done in recording other features in connection with this analysis, such as the determination of the shapes of the grains, the ratio of the percentages of each different type of shape to the whole, the surface characteristics of the grains (whether sharp, smooth, angular, ragged, rough, etc.), and the chemical, physical, and geological make-up of all the several grains, and, where possible, their specific gravities.

Microscopic examination and measurement should be used more extensively. Too little attention is now given to these features, which greatly affect the structural qualities of the soil. When the mechanical analysis curve of a given sample is recorded graphically, as is commonly the case, the results of microscopic and other examinations and measurements might well be included on the same sheet. Then, for example, when the permeable qualities of this sample are compared with those of another similarly tested, more competent and reasonable conclusions could be reached and relations between the permeable qualities and the mechanical analyses and grain shapes might be determined.

At present, a comparison of mechanical analyses curves really gives little information of the relative structural characteristics of two samples, but only the differences and likenesses in respect to distribution of sizes of the grains. The sizes determined by sieving are not even strictly comparable as the sieves do not always separate grains from one sample of the same volumetric size as those from another, because of the effect of the shape and. surface properties of the grains upon the sizes separated during sieving. This condition is true also to some extent in the measurement of finer grains by elutriation or hydrometer methods. Briefly, it is believed that the shape of the grain has fully as much influence on the structural properties of a soil as the size, and to the present time laboratory methods in general offer no adequate means of analysis and study of the effects of the shapes of the soil grains.

"Soil engineering" has advanced with rapid strides in the past decade and probably will progress at an accelerated rate in the next ten years, so it seems that the time is ripe for consideration of standardization of testing methods.

The apparatus used in the Cobble Mountain Testing Laboratory was given considerable thought as to its make-up, and careful attention as to its performance during use. The methods of determining grain-size analyses by sieving and by hydrometer or by elutriation have similarly been used elsewhere, and as these methods and the results obtained are well described and analyzed in this paper, they might well be copied in detail for use on other projects. The tests for turbidity, moisture content, and organic content are, at present, in common use elsewhere. The apparatus described for the measurement of the coefficient of friction, although not generally used, seems worthy of consideration for adaptation for future testing as it seems to have given the required results. More definite knowledge, however, is desirable regarding the effect of moisture content on tests made with this machine as well as the effect of crushing of grains during testing.

The tests for percolation, or permeability, and for porosity, however, seem to be the most difficult for engineers to agree as to which method of testing gives the most satisfactory results. Although the author did not state which of the three methods for testing permeability (the large percolator, the standpipe permeameter, and the standard compression apparatus) used at Cobble Mountain he considered the best, he did infer that any of these three would give reliable results and that results from the horizontal and vertical capillary tube methods were unsuitable.

Without attempting to discuss the pros and cons of any of these methods, the results obtained from any two of them are not comparable, as each method introduces individual features of testing. For instance, the capillary tubes are usually packed dry; many of the can type of tests are packed tacky or moist; and, for some soils, comparisons have shown that the former will give much larger percolations. Apparently, when the samples are dried there is a breaking apart of particles or grains held closely together, and the permeability is increased thereby. Tamping the samples has a marked effect on the permeable result obtained, and the moisture content during tamping increases this effect.

To obtain field and laboratory conditions of testing that will give results of the material in its natural state and in its final position in the structure, considerable judgment must be exercised in making representative tests. Care is also needed to describe the test conditions clearly in explaining the results obtained. Mixing the sample seems to decrease its permeability. The mixing seems to distribute the fines throughout the mass more uniformly in position so that the permeability of the sample is less than in its natural state. Handling the materials to be tested influences the results in such a manner that it is practically useless to discuss various apparatus until a common method of taking and handling the samples can be adopted.

However, the type of apparatus to be used must be given consideration. Large and small cans, permeameters varying in size, large tank percolators, and vertical and horizontal capillary tubes have been used with varying degrees of success. The results obtained are not comparable because each individual type has inherent characteristics that affect the results in a significant manner. It is of prime importance that an acceptable standard type of apparatus, even though not considered perfect, be generally adopted and used to aid in comparative studies of soil permeabilities.

The term, "effective size," as used by the author, is that of Hazen, and a relation between the 10% size of the core material and permeability was determined. In perusing his results, care should be taken not to confuse this term with that of Slichter because they are not alike by definition. Furthermore, the constant factor of 150 should not be used on other work because, when found for any other materials, this factor may vary as much as several hundred per cent. from that figure. In fact, it is believed that during the testing, the author must have found wide variations from the mean used, since it is extremely difficult to establish any relation between the 10% size and permeability that will hold for a range of samples, especially with varying uniformity coefficients. The use of any formula for permeability containing the term, "effective size" (meaning the 10% size), is limited, and the results obtained by its use should be regarded only as rough estimates.

Some surprisingly simple formulas for consolidation of the core and seepage are developed in the paper. Assumptions are made, however, which affect their sureness and accuracy, although they should prove useful as guides to other estimators. Drainage through the core is probably mostly in a diagonal line, while the formulas developed are based on the assumption of horizontal flow of water. The introduction of the arbitrary "effective size" gives a term in the formulas that is likely to upset their accuracy when used elsewhere, unless considerable testing is done to determine the proper coefficients.

In general, this paper, in describing testing methods, apparatus, formulas used, and results derived, offers a particularly valuable contribution to the literature available on soil testing, and this branch of soil engineering offers a large and attractive field for engineering research and study now and in the near future.

D. P. KRYNINE,[27] M. AM. SOC. C. E. (by letter).—The publication of the test procedure during the construction of the hydraulic-fill dam at Cobble Mountain has rendered valuable services not only to engineers interested in that particular kind of work, but to all who are engaged in soil mechanics research.

The writer was much interested in the comparison of elutriator and hydrometer methods described in the paper. The curves in Fig. 6 are quite close to each other; moreover, there is no possibility of giving definite preference to either of them. Since this is so and since the hydrometer is not expensive, requiring only a short time for the performance of the test, a question arises as to whether the elutriator should be recommended for future tests of the same character.

Relative to the slight difference between the curves in Fig. 6, it should be noted that the gradation curves for the hydrometer in the lower limits, show a higher percentage of finer particles than the elutriator. According to the author's statement, logically, it should be the reverse, as some of the fine particles may go down with the larger ones.

---

[27] Research Assoc. in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

In the writer's opinion, since the deviation of the curves in Fig. 6 is systematic, there should be a rational cause therefor. Probably the explanation is to be found in the conventionality of the position of the center of buoyancy. Although the curves in Fig. 4 are determined experimentally, they refer to a uniform solution or suspension, while what is dealt with in an actual case, is a non-uniform soil suspension. The center of buoyancy may be determined as the center of gravity of the displaced liquid. During the experiment, coarser particles tend to occupy lower positions than the fine ones, and, in a general case, the density of the suspension increases toward the bottom. Hence, the center of buoyancy of a non-uniform soil suspension should be lower than that of a uniform one. Owing to this fact, the actual abscissas in Fig. 4 are probably under-estimated. Therefore, this should also be true of the diameter of particles that is to be computed, using Equation (8). In other words, in a general case, a certain over-estimation of the amount of the fines seems to be inevitable.

From a practical point of view the variation shown in Fig. 6 is quite negligible (perhaps 1 or 2% by weight). An ideal "size distribution curve" cannot be obtained, and it is not worth while to spend time in refined determinations. In this connection, the writer does not see very clearly why the curves of Fig. 4 should be traced so accurately. Those curves take into account one factor only, namely, the peculiarities of a given hydrometer; but they do not pay attention to the other factor, which is the non-uniformity of the soil suspension in the cylinder. In addition, the degree of non-uniformity is changing during the entire experiment. Perhaps simple straight lines could be substituted for those curves with the same degree of accuracy as far as the final results are concerned.

The author assumes that the distance of fall of a particle in the experimental cylinder is equal to the distance from the surface of the liquid to the center of buoyancy. The writer does not possess concrete data with which to contradict this statement, but it should be noted that some investigators assume a smaller value. The U. S. Bureau of Public Roads, for instance, takes the assumed distance of fall as 0.42 times the distance from the surface of the suspension to the elevation of the bottom of the hydrometer.[28]

Different fractions of a soil may possess different specific gravities; this is especially true of fine particles. Consequently, the center of buoyancy may be displaced. This fact has never been studied.

The author compares the hydrometer and the elutriator. It would be better, perhaps, to compare the hydrometer and the pipette method; actually, the latter may be considered as a more or less reliable standard. Another test which, apparently, should not be used hereafter, is the turbidity test, because, as the author states, it has lost its value since the introduction of the hydrometer method.

---

[28] Reports on Subgrade Soil Studies, Reprinted from *Public Roads,* Vol. 12, Nos. 4, 5, 7, and 8, p. 69.

In discussing the penetration test the author states that "by applying the total load at the beginning of the test, the pipe would penetrate farther into the core than by applying the same total load in fractions at different intervals." The difference involved was a penetration of 2 or 3 ft less. This is a notable fact which is analogous, however, to the increase in resistance of a pile after rest, especially in impermeable soils. This fact is well known to both practical pile-drivers and soil-mechanics theorists. The author's Equation (2) is merely local and cannot be generalized.

Important and highly interesting experiments were made by the author in determining the coefficient of friction. The curves in Fig. 10 show clearly that the coefficient of friction of a soil is not constant, but that it depends on the outside pressure. Since the experimental data are not plotted in Fig. 10, it is difficult to say whether or not these curves tend asymptotically toward infinity when the outside pressure vanishes. This tendency is shown in Fig. 10 and is also required by Equation (18). Another solution would be an intersection of the axis of ordinates at determined finite heights, a result reached[29] by Charles Terzaghi, M. Am. Soc. C. E. The right side of Fig. 10 furnishes very consistent results which coincide with those of other investigators. For instance, Terzaghi[29] gives the value 0.52 for compacted Ottawa sand, the outside pressure being 10 kg per sq cm. Practically the same value is given by the author (load, 500 lb per sq in.).

Equation (1) gives the percentage of voids, based on the percentage of water by weight and the specific gravity of core material. In other branches of soil research, however, the percentage of water is always determined by dry weight. If w_0 designates the percentage of moisture by dry weight, the equation for determining the percentage of voids, would be:

$$V = \frac{100\ w_0\, s}{w_0\, s + 100} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

Obviously, the results computed according to Equation (1) and Equation (44) should be the same.

Another difference is in plotting results of mechanical analysis. In practically all papers dealing with dams, the coarser particles are at the right side of the diagram, as in Fig. 8; while the "size-distribution curve" used in some other research branches is constructed exactly in the opposite manner. Soil mechanics is a young science, and small discrepancies similar to those described, should be reconciled immediately.

As to the seepage formulas, there are not only formulas, but books, written on that subject. To the writer's knowledge, there is a German work, that deals with experiments on the moisture movement in the interior of an earth dam and in which attempts are made to express the results analytically.[30] Another book printed in Russian[31] is an interesting mathematical treatise discussing seepage phenomena in earth dams.

[31] "Seepage Through Earth Dams on Impervious Foundations," by Prof. N. Pavlovsky, 1932.

M. M. O'SHAUGHNESSY,[32] M. AM. SOC. C. E. (by letter).—The author is to be commended for the various devices developed in procuring information as to the texture of the core materials for this phenomenally high composite dam. A very rational method was adopted in constructing substantial toe-walls of loose rock, which are a valuable asset to any kind of an earth dam. The core material is of particularly thin section for this type of dam. The concrete toe-wall is a substantial structure, but the writer questions the wisdom of leaving such large weep-holes as 4 by 6 ft in size. A greater number of smaller weep-holes, with clean porous gravel, are far more effective.

The dam material was discharged from the mud line, the larger particles settling first, and then smaller and smaller particles until the very finest formed the core pool. The very fine particles held in suspension ultimately make up the core or water-tight section of the dam.

The Cobble Mountain Dam is the first of this type built in the East. The practice of hydraulic-fill construction has been developed successfully in the West for a great many years. This dam is a unique structure, pioneer of its particular type, and is entitled to all the success its projectors anticipate.

JOEL B. COX,[33] ASSOC. M. AM. SOC. C. E. (by letter).—The author has done a most praiseworthy piece of work in presenting the data derived from the testing program of the Cobble Mountain Dam to the profession. The time is ripe for a thorough-going consideration of the principles of hydraulic-fill dam construction, and of the possibilities of scientific design based on known physical facts. The establishment of adequate laboratory procedure is essential to this undertaking. The writer presents the following discussion in order that engineers may also have available for comparison the results obtained from a testing program at an entirely different dam, dealing with a material almost diametrically opposite in its physical characteristics from those met with at Cobble Mountain. In its scope and intent this program was considerably more extensive than that at Cobble Mountain, or than has heretofore been attempted in connection with hydraulic-fill construction. Following the precedent of the author's paper, a full report on methods used and results obtained, by Maitland C. Dease, Testing Engineer, McBryde Sugar Company, Limited, has been filed for reference with the complete manuscript of the author's paper in Engineering Societies Library.

The testing program at the Alexander Dam, Wahiawa Valley, Island of Kauai, Hawaiian Islands, completed in 1932, was developed in the belief that recent advances in the science of soil mechanics, and most notably, the work of Charles Terzaghi, M. Am. Soc. C. E., were sufficient to allow a complete analysis of the stresses within a hydraulic-fill structure and to enable design and control of construction to be based on such an analysis.

Professor Terzaghi's work[34] forms the starting point of the theoretical developments obtained in the technical control of the Alexander Dam. Early in the investigation it was found that tests did not always follow closely the rules laid down by Professor Terzaghi. The first addition to Professor Terzaghi's theory necessary to account for the observed facts was to assume that there were inter-particle forces of attraction even if the material was saturated and immersed in water.

Shearing resistance was, therefore, a compound phenomenon, being partly true cohesion, due to these little understood particle attractions and partly apparent cohesion and friction, a frictional effect caused by external load. This external load, in turn, could consist of a mechanically applied load or of a load applied by the surface tension of the water films at an external air boundary.

This recognition of true cohesion has also been made under Professor Terzaghi both by the U. S. Bureau of Public Roads[35] and at the Massachusetts Institute of Technology.

Later, it has been shown that the grains of soil cannot be considered as perfectly elastic bodies in the compression phenomena of a clay-like soil, but that their deformation is governed partly by complex frictional effects and partly by laws of plastic flow.

Other phenomena of great importance in the actual behavior of soils under stress arise from the inclusion of air in various states in the mass and in the effects of base replacement and colloidal effects due to absorption and the change in physical character coincident with a change in the acidity of the soil.

In many such relationships, it is apparent that the mineralogy of the soil, the actual chemical constitution of the various individual grains, is of the utmost importance. As yet no completely satisfactory methods have been devised for the identification of, or for experimentation with, such minerals, and much progress in the understanding of soil phenomena may be expected along these lines. No chemical analysis of a soil as a mass can be of final value without knowing how the elements are distributed in the various grains of different sizes.

In all this work, it has been apparent that great advantage to all concerned will result from a closer knitting together of the work of those who are studying soils from widely different angles. The agricultural soil physicist, the engineer concerned with soil, and the soil mineralogist and chemist can each learn much regarding his own problems by a closer contact with the work of all the others.

Specific Gravity Determination.—The pycnometer method adopted at the Alexander Dam consisted of drying the specimen 24 hours at 105° C in a pycnometer flask, adding distilled water and boiling it for 8 hours to eliminate dissolved, entrapped, and absorbed air. By using an excellent chemical balance, carefully tared pycnometers, accurate thermometers, and care in handling, results accurate to four figures can be obtained. Simple displacement methods were frequently in error as much as 15 per cent. As all subsequently determined constants are correlated with voids-ratio, an accurate knowledge of specific gravity is most important, and engineers should be warned of the difficulties and dangers of approximate methods.

---

[35] *Public Roads*, Vol. XII, pp. 89 and 117.

Permeability.—Capillary flow methods of determining permeability proved unsatisfactory at the Alexander Dam as well as at Cobble Mountain. As is apparent from the author's Fig. 15 and all other work with the consolidation of clay-like materials, the simultaneous determination of voids-ratio and permeability is necessary. No permeability determination for which the corresponding voids-ratio of the material is unknown, is of value. The criticism of the large percolator shown in the author's Fig. 14, is that the exact determination of voids-ratio is difficult, if not impossible, and, in fact, it will not be uniform throughout the depth of sample. The criticism of the standpipe permeameter (the author's Fig. 13) is that it is difficult to load with stiff and well compacted material, at the same time keeping the material homogeneous throughout. A single loading gives a determination at one voids-ratio only.

Both these difficulties are eliminated by determining the permeability in the machine devised by Professor Terzaghi on a sample for which the voids-ratio is known accurately at all times.

The clay-like laterites involved in this work may be described as soft, usually reddish, residual decomposition products of basaltic lavas or pyroclastics. They have a low percentage of silica (about 22), and are correspondingly high in iron and alumina. The specific gravity of the soil particles averages 3.2, but for individual particles the value varies widely.

Such soils are characterized by exceptionally high voids-ratios. The volume of water in such a soil is usually twice that of the solid phase even when compacted under heavy pressure. No complete explanation of this phenomenon, and of the wide range and erratic variation of this feature within a group of apparently similar soils, is available. A part of such variation is caused by the past history of the soil relating to its moisture and pressure; and compacting under pressure is shown to be a slow process which will continue to a surprising extent long after existing theories would predict a state of equilibrium. The relationship between permeability and voids-ratio is not even approximately that given by Professor Terzaghi's theory,[86] but is such that it can often be represented by the formula:

$$\log_e K_0 = c_5 + c_6 E \ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

in which, K_0 is the reduced coefficient of permeability $= \frac{K}{1 + E}$; K, the coefficient of permeability; E, the voids-ratio, or ratio of voids to volume of solid material; and, c_5 and c_6 are constants.

When plotting log K_0 against E on semi-logarithmic paper, tests on many soils will plot as straight lines, while others are concave upward and still others, concave downward. The relationship between pressure and voids-ratio follows very closely Professor Terzaghi's equations, thus,

$$E = -a_1 \log_e (p + p_c) - a_2 (p + p_c) + c \ldots\ldots\ldots\ldots (46)$$

---

[86] "Erdbaumechanik," pp. 120 *et seq.*

in which, a_1, a_2, p_c, and c are constants, and p is the unit pressure on clay, or, in approximate form,

$$E = - a_1 \log_e p + c_1 \qquad (47)$$

Usually, Equation (47) is a workable and closely approximate expression for soils.

It is interesting to compare Equations (46) and (47) with the relationships found by the author at Cobble Mountain. Equations (21) and (24) may be written, using the present nomenclature:

$$\log_e (1 + E) K_0 = c_7 + c_8 \log_e \frac{E}{1 + E} \qquad (48)$$

and,

$$\log_e \frac{1}{1 + E} = c_9 + 0.0428 \log_e p \qquad (49)$$

It would be interesting to try both sets of formulas on the original data to see which actually produces the better fit. There is little actual difference over a moderate range in voids-ratio.

It is in the investigation of chemical content, or mineralogy of soil grains, that methods and knowledge are altogether inadequate. The Hawaiian soil consists of an enormous variety of separate minerals. The specific gravity of the separate grains of a representative sample varied from 5.2 to 2.2. The identifiable grains range from magnetite to montmorillonite. It is clearly impossible to obtain much of value from the usual over-all or average determination of the chemical composition of such a soil. The most hopeful avenues of attack are to determine optically all those translucent particles for which such methods are applicable and to sort out the remainder by the use of the Thoulet solution (a mixture of solution of mercuric iodide and potassium iodide that can be given any specific gravity not exceeding 3.2) into convenient separates having approximately the same specific gravity. It is probable that further study of these separates will require the use of microchemical analytic methods.

Much of interest and importance both theoretically and practically was learned by careful microscopic examination of the soil. Many of the physical qualities most important from the standpoint of the engineer, such as crushing strength, flocculation or dispersion, and permeability can be estimated by eye by comparison with similar solids the characteristics of which are known.

A method of mechanical analysis or grading by size was developed using the direct measurement of particle diameters under the microscope. A comparison of the results of such determinations using sedimentation methods is most interesting. In every case (as is to be expected) the direct measurement gives larger grains than is computed from the sedimentation data, but the extent of the difference is very revealing of the character of the soil (for example, see Fig. 21).

The differences between the two methods of determining particle size arise from the following causes:

(1).—Visible Diameter Against the Diameter of the Equivalent Sphere.—The microscopic method measures not more than two diameters, which (due to the tendency of flat grains to orient themselves) will usually be the two greatest diameters of the grains. The sedimentation method determines the diameter of an equivalent sphere which will settle at the same rate through still water. Any tendency to irregularity or flatness in the grains will be reflected in the difference between micro-analysis and sedimentation.

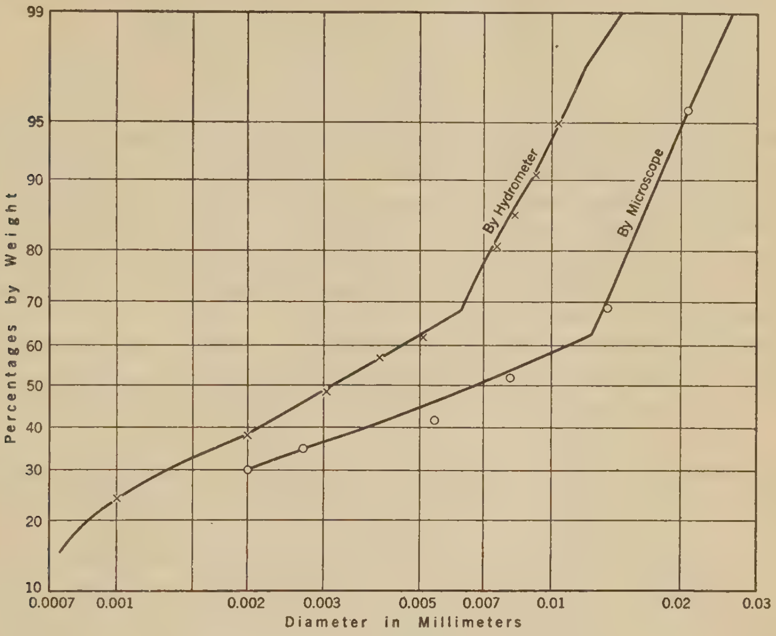

FIG. 21.

(2).—Erroneous Assumption of Specific Gravity of Particles.—The size of the particles as computed from the sedimentation analysis is governed by the specific gravity assumed. As previously pointed out, this specific gravity may differ greatly in various grains, and, therefore, any individual grain (the specific gravity of which is unknown) may differ greatly in size from that computed by sedimentation analysis, using the average specific gravity of the material.

(3).—Expanded Particle.—The excessive voids-ratio of such soils as have been studied may be due in part to excessively hydrated or expanded particles, the water of expansion of which is driven off at a low temperature and, hence, does not appear in the specific gravity determination at 110° C. Such particles will measure much larger than their speed of descent indicates.

(4).—Failure of Experimental Conditions to Fulfill Assumptions of Stokes' Law.—The sizes in sedimentation analysis are computed on the assumption that Stokes' law for the velocity of descent through still water is strictly

fulfilled. It has been demonstrated[37] that this is not strictly true for soil particles. Mechanical and electrical interactions between the particles themselves and the sides of the container give non-vertical paths, while there is a certain amount of interference from the hydrometer bulb. Slight differences of temperature set up convection currents in the liquid, and flat particles will tend to plane from side to side rather than fall vertically.

All these effects act in the same direction, to slow down the descent of the particle and indicate a smaller size than the correct value.

The really excellent check between the sizes of the sharp, hard, Kilauea volcanic sand furnishes a measurement as to the effect of Cause (4) and shows it to be small. The difficulty listed under Cause (2) will not be apparent in the average of a large sample unless a certain mineral is both lighter and tends to form larger particles than the average. The greater part of the discrepancy between the two methods of measurement appears to be conditions included in Causes (1) and (3) and both causes are significant in the physical characteristics of the material.

It was found that the relationship between permeability and voids-ratio of each one of these soils followed to a considerable degree of approximation, an expression of the form:

$$\log_e K_0 = c_5 + c_6\, E \ldots\ldots\ldots\ldots\ldots\ldots\ldots (50)$$

in which, K_0 is the reduced coefficient of permeability, in cubic meters per minute $= \frac{K}{1 + E}$; E is the voids-ratio; and c_5 and c_6 are constants.

Semi-logarithmic plotting of values of K_0 and E are shown in Fig. 22. It will be noted that, in most cases, the points fall on a straight line. A few samples give curves slightly convex downward.

Professor Terzaghi's early work on compression and consolidation of clays developed the fact that these phenomena were largely controlled by the hydraulic flow through the interstices of the material, and, at first, the time-lag of the compression resulting from the application of a given load was thought to be entirely due to this cause. Later (1928), the syllabus of the Massachusetts Institute of Technology[38] recognized that "the time effect due to low permeability combines with the time effect due to internal friction." By noting that the permeability effect varies with the square of the reduced thickness of the layer of soil, while the time effect due to internal friction is assumed to be independent of this thickness, a practical method of disentangling the two is developed. The research work at Alexander Dam, through two long-continued tests, gives additional information on this problem and suggests that the phenomenon is more complex than at first appears. One test compared the compression resulting from repeated applications of the maximum load and the rebound curves after the removal of this load. The resulting hysteresis loops are quite similar, but show a steady reduction

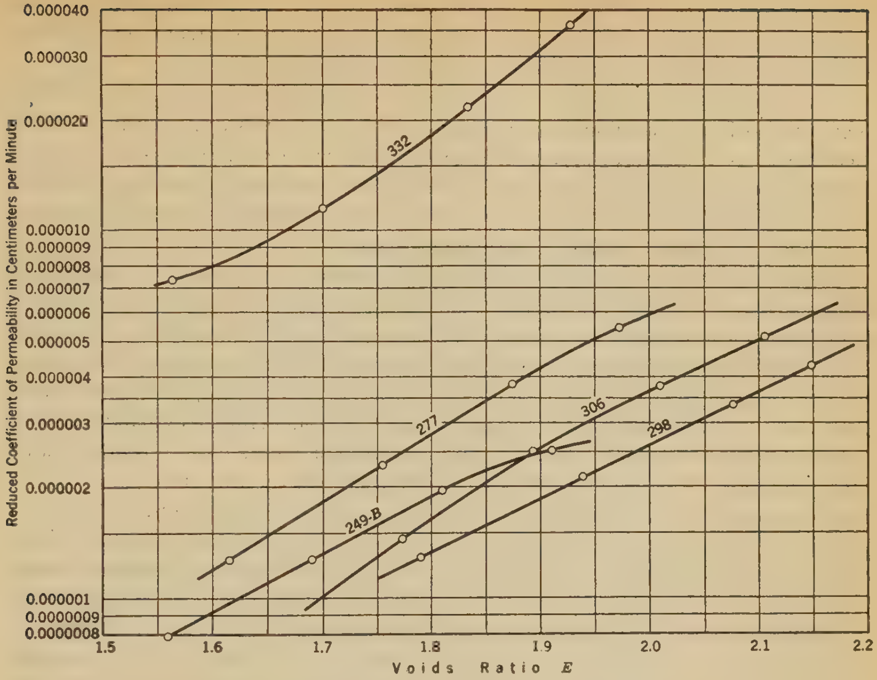

FIG. 22.—RELATIONSHIP BETWEEN VOIDS-RATIO AND PERMEABILITY OF CORE MATERIAL, ALEXANDER DAM.

of voids-ratio with successive loadings. The second test shows the slow steady reduction of the voids-ratio over many months of steady application of the same load (see Fig. 23). The results indicate that the two effects are due

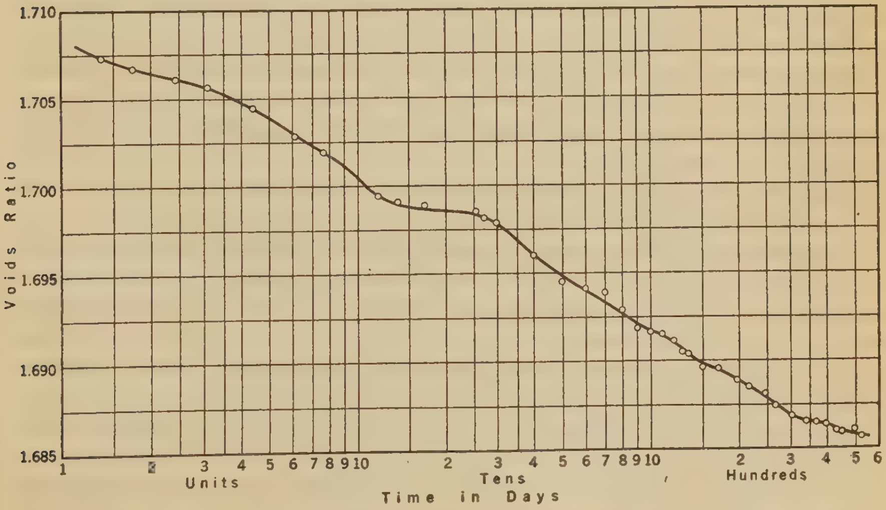

FIG. 23.—COMPRESSION UNDER THE STEADY APPLICATION OF A LOAD.

to the same cause and that the fluctuation of load is not necessary to cause increased compression. The magnitude of the long-term effect and the long period over which it continues, are most noteworthy.

The latest development in the mechanics of clay-like soils is in the related phenomena of internal friction, cohesion, and lateral pressure. Although both shearing tests and lateral pressure determination were made with simple, inexpensive apparatus (not comparable with the elaborate shearing devices developed by the Massachusetts Institute of Technology), the resulting series of values are interesting and appear significant.

For every sample for which a complete series of values is available the shearing pressure depended only on that portion of the total direct pressure which was borne directly by grain-to-grain contacts. The surplus direct pressure which was carried by hydrostatic pressure within the voids of the clay did not influence the results. In other words, if a clay sample is first tested when it is in equilibrium with its applied load, the shearing strength developed in this condition is the greatest possible without a change in voids-ratio and water content. To increase the load without allowing time and opportunity for the excess water to escape will not increase the shearing strength.

Tests of clay at moisture contents below that corresponding to equilibrium with the direct load were more erratic. At times, the shearing strength would be as great as if the full equilibrium pressure were applied. At other times, the strength would be materially less, approaching a strength directly proportional to the load. The explanation appears to be that if a clay sample contracts by drying without cracking, its interior is subjected to a pressure caused by the surface tension of the water between the grains great enough to cause it to be in elastic equilibrium; in other words, its voids-ratio is that corresponding to its actual internal pressure. Such a lump will have a shearing strength governed by this actual internal pressure, which may be many times that of the applied load. However, such a mass is too dry to be trusted not to crack, it is no longer truly plastic, and it does not always retain this unfractured state within the testing machine. Any break in the continuity of the water within its voids will release this pressure along the air and water interface, and then the shearing strength will be governed by the local grain-to grain pressure which (along this interface) is only that caused by the applied external load.

The measurements of the lateral pressure of clay with variable moisture and with varying direct pressures are likewise important and interesting. The apparatus available permitted enough water to leak past the main piston and the pressure plunger to render determinations at moisture contents higher than that at which the material was in equilibrium, with the applied load somewhat difficult and unsatisfactory. However, enough results were obtained to indicate that Professor Terzaghi's theory, that the hydrostatic pressure within the voids caused an independent lateral pressure additive to that caused by the grain-to-grain component of the applied load, was correct. This simplified the experimental problem to the determination of lateral pressure when the material was in equilibrium. To facilitate this the apparatus was rebuilt with a drainage filter in the base, and the material was loaded somewhat wetter than required and allowed to reach equilibrium in the machine. The results obtained showed a closely linear relationship between equilibrium or grain-to-grain pressure and the resulting lateral pressure. The total lateral pressure is, therefore,

$$L = Kp + w \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (51)$$

in which, L is the total lateral pressure; p, the grain-to-grain pressure within the soil mass; w, the hydrostatic pressure in water in voids of the soil mass; K the constant of lateral pressure; and $P = p + w$, the total pressure in the soil mass caused by applied load. The values of K obtained with soils at Alexander Dam, and using the apparatus available, ranged from 0.35 to 0.50.

A most important relationship with clays is that which occurs between shearing strength and lateral pressure. As shown[39] by Professor Terzaghi, the lateral pressure should be given by the following equation:

$$\frac{L}{P} = \tan^2\left(45^\circ - \frac{\phi_0}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

in which, ϕ_0 is the angle of internal friction, or $\tan \phi_0$ is the value of the shearing coefficient. The only complete series of tests on materials at Alexander Dam in which satisfactory data were obtainable on strictly duplicate and comparable samples both in shear and in lateral pressure, are given in Fig. 24.

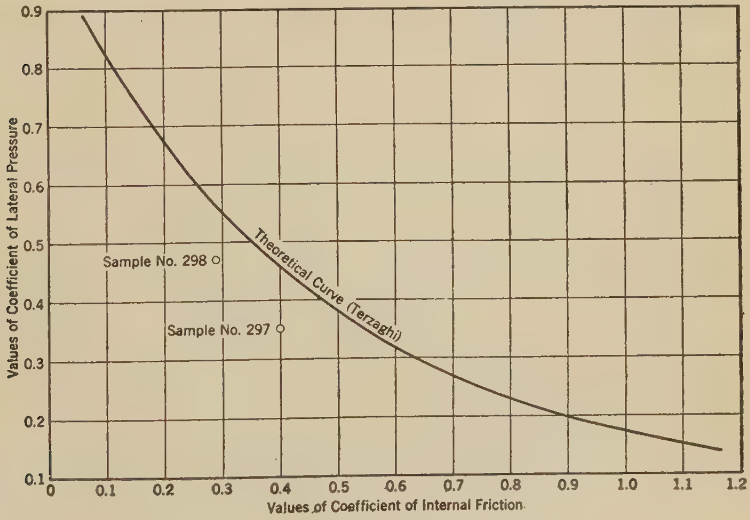

FIG. 24.

In deriving Equation (52) by means of Mohr's circle of stress, the shearing stress used must be closely scrutinized. The shearing stress developed to resist the formation of lateral pressure will be the true maximum shearing strength of the material. Not only is this the true maximum on any plane, but it is the passive or static stress. The shear measured in any test is probably not quite this pure shear, but a complex phenomenon with changing areas and distorted lines of pressure. Besides, this difference between the true maximum shearing stress which governs the formation of lateral pressure and that shown in shearing tests, there is a possibility that the internal friction of a clay, like the friction between solid surfaces, has two values, one for static, and the other for moving or dynamic, conditions. If so, the movement of the slide allowed by pure compression of the material may be sufficient to prevent a true measurement of the static coefficient of shear.

---

[39] "Erdbaumechanik," p. 188.

The physical properties of soils characterized by a granular, or a crumb-like, structure are transitional between those of clays, or colloidal-cohesive soils, and clean sands. These properties are, therefore, more complex and more variable than those of either sands or clays, and, in general, the best understanding of such phenomena is obtained by a comparison between the observed action of the crumb-like soil and the corresponding performance expected from clay on the one hand and sand on the other. It is probable that soils may be found to vary by imperceptible degrees in a continuous series from the most perfect of clays to the most cohesionless sands. The contribution of any series of tests on such soils as those at the Alexander Dam is, therefore, more likely to be of practical rather than of theoretical value and to be restricted largely in its application to nearly identical materials.

Especially to be noted is the great importance in the testing procedure of certain peculiarities of these soils, such as the great effect on shearing tests of arching within the apparatus and of compression phenomena inextricably connected therewith. The great influence of such phenomena led to a design of a testing machine and a manner of conducting tests intended to allow the estimation and correction for such effects rather than their removal. To remove arching effects very appreciably would necessitate a sample of such extremely thin section as compared to its area of shearing plane that it would lead, on the one hand, to a screening of the material to remove large lumps and particles which would render the resultant material altogether unlike that actually used in the dam, or, on the other hand, to a size of testing machine quite impracticable. Therefore, the other alternative of making control tests in which the variation of direct pressures throughout the mass of soil was measured, was followed.

The importance of compression in shearing tests is not usually emphasized in accounts of such phenomena. As actually performed shearing tests are made ordinarily on comparatively small samples either in single or double shear. As shown in Fig. 25, a considerable movement of the slide takes place by compressing the material in the darkened areas, with the toggle or arching effect of these sections tending either to increase the direct pressure (if the arrangement of slides is rigid), or to force back the material above or below (if a constant direct pressure is maintained). Before a true shearing failure takes place the shearing surface is considerably reduced in area and the distribution of stresses is complicated far beyond easy analysis. The shearing surface is no longer plane. Attempts to force shear to occur along a plane surface by grids or other mechanical restraints instead of solving the problem, only complicate it further and introduce enormous uncertainties as to the distribution of the direct pressures. Much more elaborate and thoughtful experimentation is necessary before the measurement of shearing strength may be considered as satisfactorily obtainable.

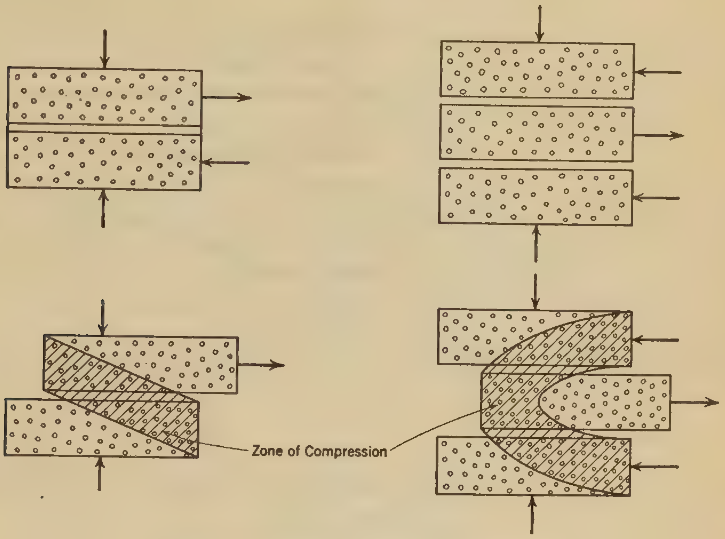

FIG. 25.—COMPRESSION DURING SHEARING.

An interesting series of tests on crumb-like soils was made to show the relationship between cohesion, moisture content, and time and pressure under which the material is packed and the cohesion developed. These are shown in Fig. 26. Cohesion was measured by means of shearing tests at light loads with an estimated correction for friction as determined from tests on the same material at varying pressures. The shearing force required, therefore, is extrapolated to zero direct pressure.

Referring to Fig. 26, the slow increase in cohesion with time after two or three days (Curve *B*), the rapid increase with pressure (Curve *C*), and the existence of moisture content both above and below which the cohesion is reduced (Curve *A*), are all clearly shown. These curves were determined by tests of the same sample under different conditions; for example, for Curve *A*, the sample was packed 2 days under a pressure of 4.97 kg per sq cm (71 lb per sq in.); for Curve *B*, the sample was kept under the same load (4.97 kg per sq cm) during the test, at a constant moisture content of 43%; and for Curve *C*, the sample was kept at a moisture content of 43% and after 6 hours was tested under various loads.

To correlate the results of compression tests in the large Terzaghi apparatus with settlements and changes in permeability observed in the dam, it is necessary to allow for the influence of larger lumps than can be tested within this apparatus. As an aid in such consideration a series of crushing tests of 2-in. cubes cut from such lumps, was run under a variety of moisture conditions. In general, an optimum moisture content is not observable with these samples. Some of them showed such an increase in strength with moderate drying, followed by a decrease as drying continued, but most samples showed a steady increase in strength down to the limit of drying obtainable in dry air. In all cases the moisture content was much lower than can be expected within the bank. Cubes cut from the soil within the borrow-pit varied in their response to soaking from those that slaked upon immersion to those showing a difference of crushing strength of 56.7% between the saturated and air-dry condition. Lumps from the Alexander Dam varied from 57% to 86% reduction in strength. Random samples showed a non-systematic variation in strength from 20 lb per sq in. to 100 lb per sq in., when soaked.

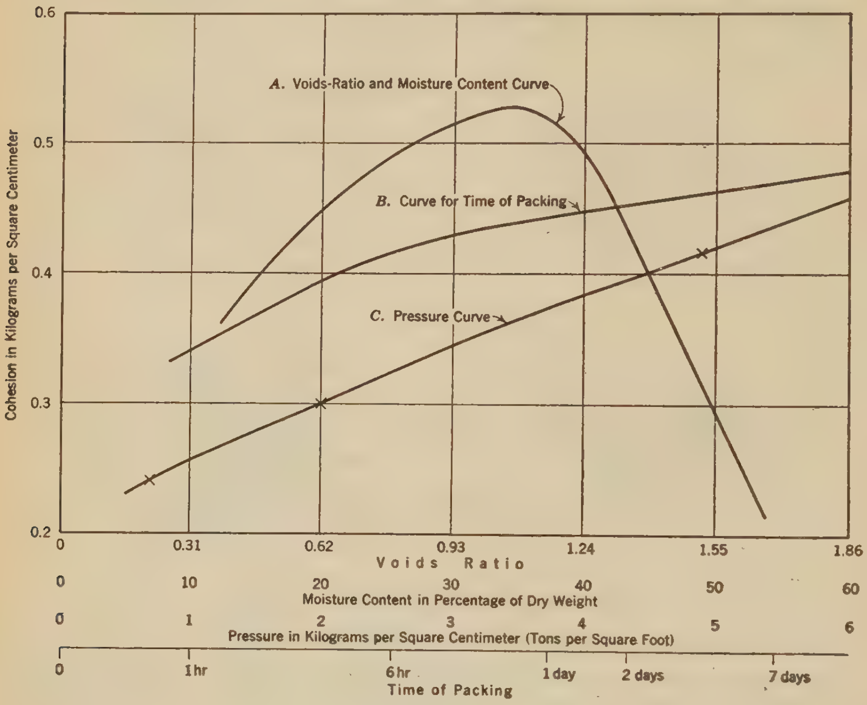

FIG. 26.

It is apparent that the settlement and compacting of such a body of earth as the beach areas of this dam, takes place not only by the compression of the finer-grained material, but also by the crushing of the coarser lumps.

The consolidation formula proposed by the author (Equation (30)) for a dam subsequent to completion is defective in its derivation. Equation (29) is based on the statement that "the rate of consolidation of the material under a given constant load, shortly after the application of the load, becomes almost uniform." This unfortunately is far from the case. This problem has been given its theoretical outline by Professor Terzaghi and has had two solutions proposed. One by Glennon Gilboy, Jun. Am. Soc. C. E.,[40] is exceedingly neat in its mathematical derivation. Its major defect is in neglecting the effect of gravity of the movement of the escaping water. The second method is one proposed by the writer for use in computing the consolidation of a dam core during construction.

It consists in separating the cross-section of the dam into a series of finite divisions and applying Darcy's law to each division separately for a short interval of time. Both divisions and time intervals must be chosen small enough to allow an average uniform velocity to be used without the introduction of too great errors.

A demonstration of the relative amount of the errors occasioned by the assumption of constant rate of consolidation is given by computing the rate of consolidation of the Cobble Mountain Dam by Professor Gilboy's method.

Taking an elliptical cylinder (semi-major axis, 5 930 cm, and semi-minor axis, 4 780 cm) that has an area roughly equivalent to that of the dam core, and a ratio of diameters about that of height to one-half the width of the actual core; and assuming an average percentage of voids of 42.8, with a Terzaghi coefficient of consolidation of 1.4, gives the following rate of consolidation:

Percentage of consolidation	Time, in days	Percentage of consolidation	Time, in days
0	0	60	501
10	21.8	70	705
20	62	80	1 010
30	134	90	1 550
40	226	95	2 085
50	365		

This is rapid consolidation, indeed, owing to the relatively coarse material of the core and the extremely narrow cross-section obtained. Even so, however, if it is estimated that 50% of the consolidation will occur during construction, the percentage of consolidation at various times after completion may be estimated, as follows:

Years after completion	Percentage of consolidation	Years after completion	Percentage of consolidation
0	50	3	88
1	71	4	93
2	82	5	96

The slowing down in rate of drainage is very marked, the drainage during the third year being only 29% of that during the first.

The writer takes exception to the argument presented under the heading "Consolidation of the Core of Cobble Mountain Dam," purporting to discredit the use of consolidation computations. Seven points are made, which will be taken up in order:

---

[40] "A Theoretical and Experimental Investigation of the Properties and Behavior of Hydraulic-Fill Dams," Thesis presented to Mass. Inst. Tech., in 1928.

(1) There is no reason why loads cannot be applied in the laboratory in any way desired, and, hence, they can be arranged to duplicate conditions in the dam.

(2) The initial percentage of voids can likewise be made anything desired when conducting laboratory tests.

(3) Two questions are raised in this connection. The first is that laboratory tests thus far have been on small-sized test pieces. The largest to the writer's knowledge have been those in the large machine at the Alexander Dam, 8 in. in diameter. These samples checked admirably with similar ones tested in the smaller machines, provided consolidation controlled by hydraulic action is separated from that controlled by internal friction. The writer hopes that more work can soon be done on large-scale and long-time tests, which will give a final answer to the question. In the meantime, nothing has yet been shown sufficient to render computations based on Professor Terzaghi's hydraulic theories so seriously defective as to be valueless. The second point is the great variability to be found in small samples of apparently similar soil. This is a fact encountered throughout the realm of soil testing, and can only be met by such a number of individual tests that their average will represent fairly that of their large-scale prototype.

(4) The rough surfaces of the beaches go down with the core as it compresses and, hence, do not retard its consolidation. The effect of abutments is certainly to complicate the process in close proximity to them, but a computation near the center of the dam will usually be sufficient for engineering purposes.

(5) The time intervals for the hydraulically controlled portion of the consolidation may be exactly computed for strict similarity. Slow re-adjustment over a long time is shown by the Alexander Dam tests (Fig. 23). This argument is precisely similar to the first point in Argument (3).

(6) The drainage facilities are capable of investigation and allowance may be made for them.

(7) The variable pressures and stresses are susceptible to computation.

Table 5 presents in compact form the great contrast in physical properties presented by the core materials of Alexander Dam and Cobble Mountain, and may well explain why methods applicable to one type will not be usable with the other.

In conclusion, the writer wishes to emphasize four points, one of which is in direct accord with the author's views while three present modifications:

(*a*) Laboratory and field determinations of the physical constants of soils are already established on a sufficiently theoretical and practical basis to serve as useful tools for the designing engineer.

(*b*) Much further investigation is urgently needed in the fields of scale effect, shearing and lateral pressure phenomena, soil mineralogy, and other phases of soil physics and mechanics.

TABLE 5.—COMPARISON OF AVERAGE PHYSICAL CONSTANTS OF CORE MATERIAL

Description	Cobble Mountain Dam	Alexander Dam
Effective size, in millimeters	0.009	0.00448
Uniformity coefficient	6.0	10.27
Specific gravity	....	3.117
Voids–Ratio; at Loads of:		
50 grams per sq cm.	1.05	2.25
3 250 grams per sq cm.	0.72	1.682
Compressibility coefficient, $\frac{1}{a_1}$	5.63	5.62
Rebound coefficient, $\frac{1}{A}$	....	77.93
Permeability coefficient (in centimeters per minute, or meters per day) at a load of 3 250 grams per sq cm.	0.000178	0.0000064
Constants for Change of Permeability:		
c_s, in Equation (45)	3.93	4.07
m, in Equation (21)	6.4	7.2
Consolidation Coefficient, for $p = 3\,250$ Grams per Sq Cm:		
c (Terzaghi)	1.88	0.0451
$C = [c(1+E)^2]$, for constant volumes	5.58	0.336
Lower liquid limit (percentage)	....	69.6
Plastic limit (percentage)	....	55.5
Plasticity index (percentage)	....	14.1
Moisture equivalent	....	57.9
Hydrogen-ion concentration, pH	....	5.9

(*c*) Although the writer appreciates the motive for the author's opinion that "it is time that a definite step is taken and a standard method developed in making tests for this particular kind of construction," he does not believe that any present method of conducting tests is of sufficiently proved superiority to be worthy of such elevation to the position of standard. The writer suggests that the most helpful course at present is to compare the constants obtained from each method of testing which is being followed, and to find the extent and reason for such differences as appear. It is the physical constants of the large-scale prototypes that are desired, and standard laboratory tests are of value only as they correlate with these values.

(*d*) All recent work on soil mechanics, using different types of soil, emphasizes the unreliability of depending on the size of grain, at least in the sizes determinable by sieve and sedimentation or elutriation analyses, as a criterion for estimating the physical constants of the soil as a whole. For most purposes direct laboratory determinations of the major constants of compressibility, elasticity, permeability, internal friction, and cohesion are necessary. One reason why the mechanical analysis of grain size is unsatisfactory as a criterion is that microscopic and elutriation methods cannot be carried into the range of colloidal grain sizes, and it is the colloidal content of many soils that governs a considerable number of its physical properties. Another reason is that mechanical analysis gives no insight into the realm of packing or structure, the importance of which is especially great in foundation problems, as pointed out by Casagrande.[41]

WILLIAM P. CREAGER,[42] M. AM. SOC. C. E. (by letter).—It is unfortunate that the theory of design of earth dams is not as exact as that for most engineering projects. The greatest contributing factor in this respect is the extreme variation in the character of the materials used in their construction.

---

[41] "Structure of Clay in Foundation Engineering," *Journal*, Boston Soc. of Civ. Engrs., April, 1932, pp. 168 *et seq.*

[42] Chf. Engr., The Power Corporation of New York, Buffalo, N. Y.

It is obvious, therefore, that material addition to the knowledge of the behavior of earth embankments subject to the pressure and percolation of water cannot be expected without the accumulation of an enormous amount of data regarding the characteristics of such materials in existing dams, tabulated in accordance with their reactions when subjected to accurate laboratory tests.

To be of value such tests should be strictly comparable. It is hoped that a method of testing materials for dams will be developed eventually, which will be as standard as those now available for most other building materials. The author's presentation of the testing methods used at Cobble Mountain Dam is very commendable and may well serve as a basis upon which to develop a standard method.

The writer is much interested in Equation (23), particularly in regard to the exponent of V. From this equation it is seen that the author's experiments indicate the relation between the coefficient of permeability, K, and the percentage of voids, V, to be expressed by the formula,

$$K = C\,V^{6} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

Prior to the publication of the author's paper, the only authority for the relation between these two factors was that given by Professor Slichter,[43] as,

$$K = C\,V^{3.33} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (54)$$

and this relation has been used extensively in textbooks. There is probably some explanation for this difference, either in the method of testing or in the class of materials used.

Harry H. Hatch,[44] M. Am. Soc. C. E. (by letter).—The purpose of tests for hydraulic-fill dams is to determine certain characteristics of materials that bear directly on the safety or the design of the structure, as mentioned throughout the paper. The standardization of tests and the development of new testing methods naturally will lead to more careful consideration of the requirements of design as pointed out by Mr. Paul, who states that,

> "Core material available is limited approximately to the quantity passing the 200-mesh sieve. An excess over apparent requirements is necessary, as some of the fines will be trapped in the beaches, and it helps core control to be able to waste some of the fines"[18].

This cannot be true in all cases and should not be taken as a general principle.

The gradations of various core samples tested at Cobble Mountain (see Fig. 8), show the wide range of the percentage of material passing the 200-mesh sieve. The curves for the upper range, which show that almost 100% of the core consists of material that passes a 200-mesh sieve, are from dams in which fines have possibly been wasted during construction. In some of the dams represented in the lower ranges, the limit being only 50% of the core made up of material that passes a 200-mesh sieve, no fines were wasted during construction. No doubt there are other successful hydraulic-fill dams with cores that contain less than 50% of material finer than a 200-mesh sieve (ignoring any waste material), in which there are not enough fines to prevent excessive seepage.

---

[43] *Water Supply Paper 140*, U. S. Geological Survey.

[44] Engr., in Chg., Cobble Mountain Reservoir, Springfield Water-Works, Blandford, Mass.

The gradation tests of eight borrow-pit samples of hydraulic-fill dam material analyzed at Cobble Mountain showed that the range of variation of the material in the borrow-pits that passes a 200-mesh sieve, was about 700% between the finest and the coarsest samples.

The clay content and the distribution of particle sizes or the gradation of the material passing the 200-mesh sieve are of utmost importance.

Excess quantities of fines in the borrow-pits, greater than the requirements of the core, are not always desirable. In fact, in some cases this condition is a source of trouble and danger. Not much fine material could be wasted in the beaches. No doubt some will be trapped here and there, but in quantity it has no importance. If considerable quantities of fine materials are deliberately entrapped in the beaches, it will create a source of weakness in the structure.

For the construction of the Cobble Mountain Dam the contractor was limited to certain prescribed borrow-pits. After the first working season (1929), when the structure had been built to a height of about 60 ft, the contractor located another borrow-pit, which was much to his advantage in regard to elevation, location, depth, quantity, etc. However, the material contained excessive fines, such that the percentage passing a 200-mesh sieve was approximately the same as that of the material in the core of the dam.

The contractor was told of the restrictions in the specifications, justified for various reasons, that no excess fines could be wasted below the dam. Extensive studies were made to provide special storage basins within or outside the reservoir basin for depositing these fines. After much time and thought spent on the proposition, the idea was abandoned because of its exorbitant cost and the impracticability of taking care of the excessive fines in the proposed storage basins.

In 1930, the contractor insisted on giving this material a trial and subsequently moved about 35 000 cu yd of it. Between the heel of the dam and the entrance of the diversion tunnel, a dike was constructed near the intake, to separate the supply pool or the settling basin from the Springfield (Mass.), Water Supply System during the construction of the dam. It was hoped that sufficient fines would precipitate in this settling basin, but in spite of all precautions, some were wasted below the dam, causing much trouble.

Immediate difficulty was encountered because the core section was built faster than the beach and not enough water was left in the core pool to float the pumps. The fines did not precipitate as readily in the settling basin as had been expected and, since the muddy water was used over again, it became almost impossible to operate the plant due to the fines being carried back and forth. To proceed with the operations meant increasing the depth of the core pool which, necessarily, would increase the width of the core.

Furthermore, the fines in this material were such that the slopes of the beaches were flat. These factors combined to produce layers of very fine material within the beach section, such that the safety of the structure was threatened, and work had to be stopped. Remedying the situation, the dam was finished with material from the borrow-pits originally specified.

Each construction job has its own problems, and these problems often vary greatly, especially as to the feasibility of wasting excessive fines. At times the quantity of water, that is necessary for wasting fines, must be considered. It is of the utmost importance to know the problem; that is, to know the nature of the material available—the conditions and the restrictions governing its use—and then to design the structure accordingly.

A comparison of the gradations of core materials in Cobble Mountain Dam with those of the Miami Conservancy dams cannot be conclusive in discussing their relative consolidation and seepage without taking into consideration the respective heights of the dams and the widths of the core sections. The maximum height of the Cobble Mountain Dam is 263 ft, compared with a height of 125 ft for the Englewood Dam, the highest in the Miami Conservancy District.

Equation (30) takes into consideration the conditions after the completion of the dam. There is no dispute concerning the vertical drainage prior to completion, but no one can state definitely how much vertical drainage occurs afterward. Whatever that may be, it can properly be assumed that the drainage of the remainder of the excess water (or the ultimate consolidation), will take place approximately in accord with Equation (30), keeping in mind the assumptions and limitations given in its derivation.

Assuming that the two dams under consideration are built with identical materials and under the same conditions, and considering only the effect of the height and width of the core and the effective size of the material, Equation (30) becomes:

$$T = \frac{c}{H} \frac{D^2}{d^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55)$$

in which, c is a constant. Substituting values pertaining to Cobble Mountain Dam in Equation (55),

$$T_1 = \frac{c}{263} \frac{(170)^2}{(0.009)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56)$$

Substituting the effective size pertaining to Miami Conservancy dams in Equation (55) and adopting the Miami Conservancy design of core width at any elevation equal to the height of dam above that elevation, and with the height of the Cobble Mountain Dam,

$$T_2 = \frac{c}{263} \frac{(263)^2}{(0.002)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

The ratio of T_2 to T_1 (Equations (57) and (56)) indicates that the Cobble Mountain Dam, with Miami Conservancy design and core material, would require 48.5 times as long for ultimate consolidation as it will under the existing conditions. The fact that the core material used in the Miami Conservancy dams showed a satisfactory rate of consolidation would not necessarily mean that the same material would show the same satisfactory consolidation if used in a dam as high as that at Cobble Mountain.

Mr. Paul offers no data pertaining to the angle of repose of materials in successful hydraulic-fill dams and their outer slopes to show that "in many cases other considerations, such as angle of repose, may require a volume of shoulder material that will eliminate the necessity of more than a passing consideration of the coefficient of friction." The outer shoulder slopes of hydraulic-fill dams are built to designed grades, usually by dikes made from sluiced beach material. During construction the dikes near the outer slopes of the Cobble Mountain Dam were built from sand and gravel excavated at the discharge end of the sluicing pipes and dumped by the drag-lines. The slope of the angle of repose of these dikes was less than 1 on $1\frac{1}{2}$, and yet the average down-stream slope of the dam was 1 on $3\frac{1}{3}$ and the average up-stream slope was 1 on 3. As emphasized in the paper, the coefficient of friction is one of the most important factors in the design of hydraulic-fill dams.

Mr. Paul's remarks in regard to prevention of tongues or layers of sand or gravel in the core and the seepage through abutments and foundations are very important. However, these are construction and control problems, and even though not exactly within the scope of this paper, the writer's remarks in another paper[45] may be repeated here, namely, (1) the engineer should have a thorough knowledge of the functions of the constituent parts of an hydraulic-fill dam under construction; (2) constant watch should be exercised both at the borrow-pits and at the dam to see that the quality of the structure is not affected; (3) the coarse material in the core section can be moved out and spread over the beach areas by means of drag-lines; the material which the drag-line cannot reach can be agitated and dispersed among the fines of the core section by means of jetting apparatus shown in Fig. 27; (4) in order to insure a good bond between the hydraulic-fill and the sides of the gorge particular care was taken, especially within the core area, to remove all surface cover; (5) it was soon discovered that if the surface cover within the core section was sluiced into the core pool, the fines would disperse all over the core area and leave the coarse material next to the sides of the gorge, creating blind drains; all such coarse deposits next to the sides were removed and, later, all the excavation was carried from the core area to the beaches; and (6) it is important to secure the required degree of water-tightness in the foundation both at the bottom and on the sides of the dam by cut-off trenches, cut-off walls, and grouting.

Answering Mr. Justin's question in regard to the costs of the tests and control, it should be stated that the research at Cobble Mountain, both in the laboratory and in the field, was undertaken with the full advantage of the practical and theoretical knowledge of several authorities on the subject. Even then, not enough definite information for all the necessary tests could be obtained. From the beginning to the end, no method dealing with the problem at hand, developed elsewhere, or contemplated by others, was either adopted or discarded until it was given a satisfactory trial. Members of the Laboratory Staff were sent to Columbia University and Massachusetts Institute of Technology to get acquainted with the research being done by others along similar lines. Almost all the important hydraulic-fill dams under construction in the United States were visited and problems and methods of testing were studied in each case. Several sets of apparatus were purchased and used for tests, but their cost as well as the time lost in making the experiments produced nothing of value except the knowledge that the tests were not suitable for the purpose. The cost of some of the testing machines developed on the job was only a fraction of the total expense incurred for the necessary preliminary investigations leading to the development of the final design and construction. Due to delay in the construction, because of re-letting the job to other than the original contractor for the completion of the dam, the available extra time was used to advantage for field and laboratory research, which would have been impossible had the construction progressed continuously. Due attention was paid to field control which is no less, if not more, important than laboratory control. The cost of the equipment was more than $5 000. There is no doubt that the control practiced at Cobble Mountain Dam was elaborate, but with reason; and it was certainly expensive if the cost of the aforementioned factors is taken into consideration.

FIG. 27.—JETTING EQUIPMENT TO DISPERSE LAYERS OF COARSE MATERIAL IN THE CORE DURING CONSTRUCTION.

A maximum number of three technicians was employed at the Cobble Mountain Laboratory. A fair estimate of cost for only laboratory control at Cobble Mountain Dam, without considering the training of the men, preliminary investigations, and experiments, would be about $15 000, or, say, nearly 1 cent per cu yd of hydraulic fill in the dam.

The samples showing the percentage of voids of the core (Fig. 2) were taken at about 15 ft below the silt or mud elevation and about from 15 days to 1 month after the material had been placed. The core material deposited in the bottom of the pool had about 60% voids.

There is a constant change in the percentage of voids in the core at any one elevation, due to the increased weight as the construction progresses. Without undue expense, the percentage of voids of the core material at various elevations at the completion of the job cannot be stated exactly; but an average approximate value from observations during construction can be selected similar to that following Equation (30) of the paper, where the assumption is that the percentage of voids in the core will vary from 50% on top to 45% at the bottom, and that the approximate average is about 47.5 per cent. These values, however, will not necessarily apply to other cores.

Under a given load for a given material there is a limiting ultimate percentage of voids that remains almost constant, as expressed by Equation (24) for the local material, keeping in mind the conditions noted in the paper.[46]

With an assumed average percentage of voids and with a given specific gravity of solid material, the acting force, L, in Equation (24) at any one elevation below the top of the dam can be computed by means of graphs similar to Fig. 28. With the assumed and final percentage of voids, the approximate time necessary for ultimate consolidation can be computed by means of Equation (30) similarly to the numerical problem immediately following that formula.

Mr. Justin's reference to Mr. Hazen's investigation of the Calaveras Dam evidently applies to the latter's statement:[47]

> "Without attempting precision of statement, it is the writer's judgment that if core material like that at Calaveras could be consolidated to 40% of voids, it would be sufficiently stable to do its share toward resisting the pressures that come on the dam without tending to disruption. Perhaps this degree of stability would be reached before consolidation had proceeded as far as 40% of voids. There is a middle ground of uncertainty. Material with 50% of voids is still unstable; and between this limit and 40% one cannot be certain just where to draw the line."

Mr. Hazen did not state, nor does Mr. Justin state, at what elevation in the Calaveras Dam, or under what given load, the 40% of voids is desirable; nor are there any data to show the ultimate rate of consolidation under various loadings, or at various heights of the dam, for the Calaveras core material.

---

[46] See p. 240.

[47] "Hydraulic-Fill Dams," by the late Allen Hazen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 1720.

The twenty-eight core samples tested at Cobble Mountain under a pressure of 200 lb per sq in. showed a wide range in percentage of voids at ultimate consolidation. The minimum was 30% and the maximum, 41.5%, depending on particle sizes and other characteristics of the same materials. The percentage of voids at ultimate consolidation cannot be uniform throughout the core, since naturally it is a minimum at the bottom and increases gradually, depending on the uniformity of the material, toward the top of the dam.

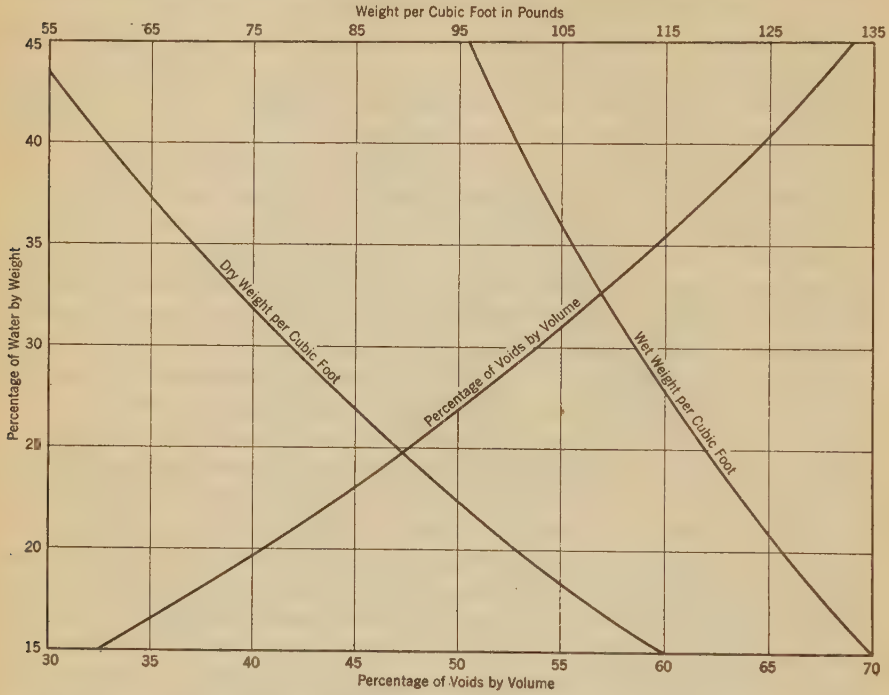

FIG. 28.—CURVES SHOWING RELATION OF WATER CONTENT TO PERCENTAGE OF VOIDS, AND WEIGHT PER CUBIC FOOT FOR SATURATED MATERIALS. SPECIFIC GRAVITY OF SOIL PARTICLES = 2.72.

The local material for which Equation (24) was obtained, has an average of about 38% of voids at ultimate consolidation under a loading of 200 lb per sq in., corresponding to the maximum pressure at Cobble Mountain Dam. At a pressure of 100 lb the same material will have 40%, at 50 lb, about 41.7%, and at 25 lb, about 43.5% of voids for ultimate consolidation. There is every reason to believe that the percentage-of-voids curve for the core, as obtained from Equation (24), is too low, and that actual consolidation in the dam can reasonably be assumed at a percentage of voids about 10% higher. The handling or the puddling of the sample while being placed within the compression apparatus produces a somewhat different arrangement of the particles, resulting in a lower percentage of voids in the material. This, according to the reasons already given in the paper under the heading, "Consolidation of the Core of Cobble Mountain Dam," will result in a lower final percentage of voids. The initial percentage of voids of the local material in question, before application of any load in the testing machine, was about 53%, whereas the initial percentage of voids of the same material in the bottom of the core pool is about 60 per cent.

Undoubtedly, it is desirable that, soon after construction, the core material shall have been almost completely consolidated under various loadings, at different elevations in the structure.

The statement in the paper that "there is no such general formula giving the seepage through any hydraulic-fill dam" similar to that proposed, was made with full knowledge of the formulas previously given by Mr. Justin "for seepage through earth dams and also for seepage through the foundation soil." Mr. Justin's formulas, which are adaptations of the Hazen and Slichter formulas, are cumbersome, are not general, and cannot be applied to the core materials under consideration.

The Hazen formula (Equation (22)), for the filter sands cannot be used for core materials. Without going into detail, briefly it may be stated that Mr. Hazen's constant varying from 400 to 1 200, applicable though it may be for filter sands, cannot be applied to core materials. The Hazen formula does not have any factor to take care of the variation in the percentage of voids of the material. It may be claimed that filter sands are more or less alike, and perhaps that they have a uniform percentage of voids; but the same argument cannot be applied to the core materials of hydraulic-fill dams in which there is such a variation in the percentage of voids. Furthermore, the effective size and the 60% size of filter sands cannot be compared with the respective sizes of core materials in hydraulic-fill dams. Here, again, the conditions are different.

Professor Slichter refers to his own formula for determining the flow of water through a column of sand,[48] but he does not state how he devised it. In the absence of any definite information, and in view of the fact that his discussion refers to sands and to the Hazen formula, the writer believes that Professor Slichter's formula will not apply to core materials.

The formula may be valid for sands within the range of sizes used in the Hazen experiments, but it is doubtful whether it will be reliable for fine particles of about 0.01 mm, as given in his tabulation of "transmission constants."[49] His results are probably due to theoretical computations, and his experiments, if any, did not cover the lower ranges given in his table. It is doubtful whether, about 1900, gradations were made as fine as 0.01 mm. The "transmission constants" tabulated by Professor Slichter, indicate that the value of K varies approximately as $V^{3.3}$, whereas Cobble Mountain experiments for core materials (Fig. 15), show that K varied as $V^{5.40}$ to $V^{7.2}$, or approximately as V^{6}, which is the average value adopted in Equation (23).

In the preceding three paragraphs will be found the reasons for the differences in Equations (53) and (54), as pointed out by Mr. Creager.

---

[48] *Water Supply Paper No. 67,* U. S. Geological Survey, p. 24.

[49] *Loc. cit., No. 140,* U. S. Geological Survey.

Mr. Wade's discussion of the theory of the hydrometer is a valuable contribution on the subject. It would be desirable to have complete knowledge of the underlying principles of the hydrometer; to know exactly what is taking place during the test; why the particles do not settle according to theoretical calculations; the effect of the Brownian movement; whether there is any vortex motion; and what the real reasons are for the variation in results obtained by the hydrometer compared with those by more accurate methods. These factors are not well known yet, and any possible attempt to discuss them theoretically would have been outside the scope of the paper. More space has been given to the hydrometer than is warranted, when it is considered that the hydrometer method is only one among several for making gradation tests, and that the latter is only one of the many subjects treated in the paper.

Certain principles were given to explain reasons for the method of conducting the tests, and certain probable causes were enumerated for some of the variations of the obtained results compared with those by other more accurate methods.

The adoption of the hydrometer method, with reasonably accurate results, as described, will depend perhaps more on the simplicity and almost negligible cost of the instrument, and the speed of the tests, rather than on an immediate thorough knowledge of the underlying theory.

Quite properly, Mr. Wade points out the possibility of confusion in interpreting the statement pertaining to concentration at the center of buoyancy. This would have been clear perhaps if it had been stated that the resultant buoyant forces of the uneven concentrations at various elevations in the suspension acting on the hydrometer are observed arbitrarily at its center of buoyancy.

The assumption that the center of buoyancy is the critical point to which to measure the depth below the water surface, seemed logical and gave satisfactory results, even though there was "a slight error in the assumption," according to Mr. Wade.

By checking the readings of the hydrometer with various predetermined quantities of grammes of soil per liter of water, or with solutions of known concentration, as recommended under the heading "The Hydrometer," Mr. Wade's problem with respect to variation in the specific gravity of the material in suspension can be avoided. It is doubtful whether there will be any change in the specific gravity of a core material, during the process of settlement, provided this material is nearly free of organic matter, and provided the particles of soil in the sample are of a practically uniform specific gravity.

The dispersing agents used at Cobble Mountain were mostly ammonia, sodium oxalate, and sodium silicate. The proper quantity to be used for a given soil sample can be obtained by trial beginning with a small quantity and increasing it gradually until the right proportion is reached.

The hydrometer and the thermometer readings can be estimated to the nearest one-tenth, and no doubt the nearest one-half gramme or one-half degree would suffice. Even though the corrections made on the hydrometer readings in Table 3 could have been neglected, they were inserted to show the arrangement of observations and the method of computation.

At 68°F the viscosity of water was assumed to be 0.01005 poises, or 1.005 centipoises. It is desirable, of course, to have water in the graduate with a temperature of 67°F in order to avoid corrections entirely, which, otherwise, should be made according to Equation (10). The corrections can easily be obtained from a graph of this equation.

In addition to the gradation, Mr. Dore suggests making determinations of grain shapes, their classifications, their surface and other characteristics. This would tend toward a high degree of academic refinement; but, no doubt, such studies made in a research laboratory would be of value in construction work if and when they can be readily applied in a practical manner. It is doubtful whether they can be included among the tests to be made in the field laboratory during construction. It should be remembered that laboratory and field control must supply data for quick and decisive action because of extreme variation of the characteristics of the material on hand and the urgent necessity of speed.

The surface characteristics of the grains, and their hardness are of great importance, and periodic examinations by microscope and otherwise were run at Cobble Mountain, with the result that important changes were made during construction. It is obvious that the information will be more complete if various characteristics and properties of the material in question could be presented in an accepted and compact form. It is to be hoped that investigation of the coefficient of friction of earth dam materials will continue until sufficient data are obtained on this subject.

The merits and the limitations of the three methods of testing for percolation, as finally adopted at Cobble Mountain Dam, were stated in the paper. Each has its own advantages, depending on the available time for tests and consideration of cost. It was fortunate that at Cobble Mountain each of these methods was available and was used, because some of the results obtained and conclusions reached are due to their collective use.

In regard to the vertical and horizontal capillary tube methods, it may be stated that the dry sample of material placed in a glass tube cannot be converted into a material similar to that in the core of a dam. The dry sample often contains small lumps of material that are not broken up even with reasonable care in its preparation. The lump content of samples is not the same, and it does not follow any rule. The presence of lumps accelerates the capillary rise of water in the sample in proportion to their size and number.

These methods are more or less approximate. The vertical capillary method requires a series of master curves, prepared carefully for similar materials, and by elaborate methods. The horizontal capillary formula contains a constant, depending on the percentage of voids and the character of soils, which can only be obtained after the coefficient of permeability of that one material has been determined carefully by numerous experiments conducted with reliable methods. The fact that similar approximate values or results could be obtained more easily and readily from Equation (23) was the reason for discarding them without prejudicing their value for testing rolled earth dam material.

It was not intended that Equation (23) should replace the actual tests and direct measurement of the coefficient of permeability of the core material, but that it should be used only for estimating, approximately, the coefficient of permeability. This formula is the best tool available for the purpose. In order to be of more general use in its application to the wide range of core materials, it requires a factor, expressed in terms of the area, perhaps below the curve, between size limits of 60 and 10%, or (which is better) as nearly as possible between the full limits of 100 and 0 per cent.

The relation between the coefficient of permeability, K, and the effective size, d, as shown in Equation (23), was obtained from the results of thirty-nine complete experiments using two different sets of percolation apparatus. A study of the plottings of Fig. 29 will show that for the large percolator the range of the coefficients is from 84 to 480 and the general average for the 18 tests is 176. The compression apparatus gives a range of coefficients from 30 to 311, or a general average of 106 for 21 tests. The average of the values obtained from the two sets of apparatus is 141.

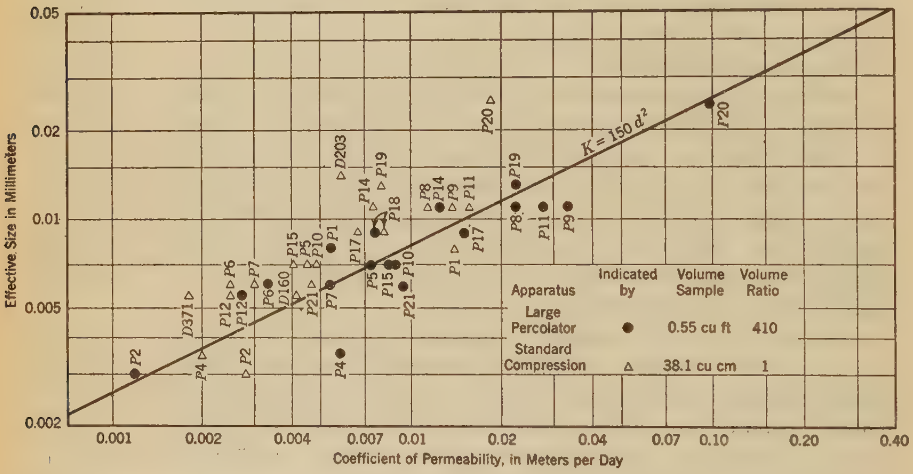

FIG. 29.—RELATION BETWEEN EFFECTIVE SIZE AND COEFFICIENT OF PERMEABILITY AT 45% VOIDS AND 50 DEGREES FAHRENHEIT.

The following test results were questioned during the experiments:

Sample No.	Value of K	Apparatus used
$P1$	228	Standard compression
$P2$	311	Standard compression
$P4$	480	Large percolator

Omitting these questionable data, the range of the coefficients is from 84 to 278 for the large percolator and the general average for the reliable 17 tests is 157. Similarly, the range of coefficients is from 30 to 163, for the compression apparatus, or a general average of 89 for 19 tests. The average of the values obtained from the two results is 123.

The adoption of *K* equals 150 instead of 141 or 123 is due to preference given the large percolator, which may be more reliable for this test in view of the fact that its sample was more than 400 times larger than that used for the compression test. Equations (23), (30), and (43) afford valuable information if used with discretion, keeping in mind their restrictions or limits as pointed out in the paper.

Due to the fact that the gradation results obtained by the hydrometer and elutriator methods are almost alike, Professor Krynine raises the question as to why the elutriator needs to be used for future tests of the same character. At Cobble Mountain, hydrometer results were often checked by the elutriator, thus making certain that the hydrometer results were reasonably accurate. If the hydrometer runs at a construction laboratory can be checked periodically by a more accurate method, whether the elutriator or some other, there is no reason to invest money in the apparatus and devote time to making elutriator tests.

Attention is called to some facts in regard to the arbitrary assumption relating to the center of buoyancy of the hydrometer bulb, which, when fully studied and analyzed, may clarify further the reasons of the discrepancy (especially in the lower limits), between the results of the hydrometer and a more accurate method.

The curves in Fig. 10 were plotted only within the limits of actual experiments, and the corresponding equations are likewise limited. It seems logical, however, that as the vertical pressure approaches zero the coefficient of friction should approach infinity.

It is regretted that Professor Krynine did not reproduce from German and Russian books on seepage, a formula, if any, similar to Equation (43), that would give the seepage through a hydraulic-fill dam. It would be interesting to compare such a formula with Equation (43) of this paper. Equation (43) was derived without any knowledge of the works referred to by Professor Krynine.

Mr. O'Shaughnessy states that "the core material is of particularly thin section for this type of dam." This is true for Cobble Mountain Dam as compared with others in existence. The thin core section has given good satisfaction, however; the reservoir has been full for some time and the seepage through the structure has been negligible.

The large weep-holes in the toe dam will scarcely affect the resisting strength of the structure, and there is no danger of their being plugged by fine material, resulting in hydrostatic pressure back of the toe dam.

According to Mr. Maitland C. Dease, to whose report Mr. Cox refers, considerable work has been done at the Alexander Dam along lines suggested by Professor Terzaghi for tests on clays. These methods were not given much consideration at Cobble Mountain, because the problem was not concerned with clays. The "scope and intent" of the testing program at Cobble Mountain Dam was practical, and was as complete as possible.

Highly theoretical tests made in research laboratories, are valuable, but in the construction of an hydraulic-fill dam the most important criterion is effective field control, guided by laboratory tests. The laboratory investigations for this purpose should bear immediate results, which, in turn, should become useful for immediate application. The interpretation of the laboratory and field investigations is of utmost importance. Neither elaborate machinery, long-period tests, nor complicated equations are necessary in order to detect danger signals pertaining to the safety of the structure. Simple terms, common sense, and practical judgment in interpreting tests are more valuable than tests requiring months, which produce complex equations not readily understood. Lack of practical interpretation often leads to disastrous results, no matter what the testing program may have been.

The aim at Cobble Mountain was to simplify the testing methods and to make frequent tests so that their results could serve as guides during the construction. Changes were possible immediately, without hindrance to the progress of construction, and yet with time to produce the required stability in the structure.

A study of Mr. Dease's full report reveals no information in regard to the number of tests for the coefficient of friction at Alexander Dam comparable with about 550 tests made at Cobble Mountain Dam. The report indicates that during a month only six core samples and only three beach samples were tested, whereas at Cobble Mountain Dam an average of more than 100 core samples alone were tested each month. There is no evidence in the report to substantiate Mr. Cox's statement that the testing program at Alexander Dam "was considerably more extensive than that at Cobble Mountain, or than has heretofore been attempted in connection with hydraulic-fill construction."

Shearing resistance of beach material is of interest; no studies of the effects of cohesion and friction in their combined relation to shear were needed at Cobble Mountain, because the beaches were composed of almost cohesionless sand and gravel.

Whereas a material as fine as that used in the Alexander Dam might require the pycnometer method for accurate determinations of the specific gravity, the simple displacement method gave entirely satisfactory results with the coarser and less cohesive material used in the core of the Cobble Mountain Dam. On the other hand, considering that at Alexander Dam "the specific gravity of the separate grains of a representative sample varied from 5.2 to 2.2" (a variation of 236%), it is questionable if it was necessary to use such refined methods of determining the specific gravity, because the "simple displacement methods were frequently in error as much as 15 per cent."

The voids in the large percolator described in the paper were obtained with sufficient accuracy by simple moisture content determinations, and the variation within the apparatus was measured and found to be insignificant.

The stand-pipe permeameter is admittedly difficult to load with some types of material and under some conditions and hence it is limited in its application, but where it is suitable, it is simple and quick.

The term, "percentage of voids," is preferred to that of "voids-ratio," because of its simplicity, and because of the fact that it has been used for many years and is readily understood by practising engineers.

The simplicity of Equations (21) and (24) compared with Equations (46) and (47), speaks for itself especially when "there is little actual difference over a moderate range of voids-ratio." Both sets of formulas are empirical, and are applicable to particular materials. The ultimate aim might be to develop a set of formulas sufficiently general and complete to cover all materials and containing commonly accepted terms. Until such formulas are available the most simple, rather than the most technically precise, formulas would seem desirable for working purposes.

A study of the curves in Fig. 22 shows that they can be expressed by the general formula given in Equation (21), but that the exponent, m, will be much higher than 7.2 as given in Table 5.

The permeability coefficients in Table 5, evidently do not take into consideration the temperature factor, which is important.

The permeability coefficient given for the Cobble Mountain Dam material is not correct, and, furthermore, the units of centimeter per minute and meter per day are not the same. Chemical content and mineralogy were not serious problems at Cobble Mountain Dam, but their importance as pointed out seems evident, and of considerable interest.

The time required for reasonably accurate work by microscopic examination makes this more properly a research, rather than a field laboratory, test. Due to the relatively uniform specific gravity of Cobble Mountain Dam material the difficulty with variations was not encountered; there was no indication of excessive hydration. The other factors are undoubtedly present and their influence depends on the character of the material. These factors must be estimated for material from any given locality, since they are not susceptible at present to complete, or exact, analysis. The discrepancy in the gradation curves obtained by hydrometer and microscope, as shown in Fig. 21, is interesting, if these curves are the results of numerous sets of experiments.

The discussion of shearing tests on clays and clay-like soils is of considerable interest and possible value in soil studies. Its importance with direct relation to an hydraulic-fill dam is not so evident. The fundamental concept of a true hydraulic-fill dam is one in which the beach section is of a sufficiently coarse material to permit almost immediate drainage and consolidation of itself, such as to allow suitable drainage facilities for the core. The safety of an hydraulic-fill dam being dependent on the coefficient of friction, or shearing resistance of the beach section, the application of shearing tests to this coarser material would seem more important and applicable.

Fig. 30 (in which the curves are similar to those of twenty-six other sets of consolidation experiments made at Cobble Mountain) and Table 6 will substantiate the statement that "the rate of consolidation of material under a given constant load, shortly after the application of the load, becomes almost uniform." For example, Table 6 shows that 100% consolidation was reached for Curve *A* in 20 hr, whereas, by Fig. 30, the sample had 97% consolidation in 10 min. Likewise, Curve *B* reached 100% consolidation in 19 hr (Table 6), whereas the sample material reached 80% consolidation in 10 min. This rapid consolidation undoubtedly is due to the physical characteristics of the Cobble Mountain material. Perhaps the conditions would be different for clays, but the same tendency is evident in Fig. 31, which was replotted from Fig. 23 for Alexander Dam material. In the absence of any definite data in regard to the initial and final voids of the sample material, assume that they conform to the limits of the plotting in Fig. 31; that is, assume that the percentage of voids was 63.065% when the load was first applied and 62.767%, after the material had become completely consolidated. The consolidation is very rapid at the beginning, and for almost the last half of the total time required for the ultimate consolidation of this material there is no reason why the rate of consolidation could not be assumed as "almost uniform."

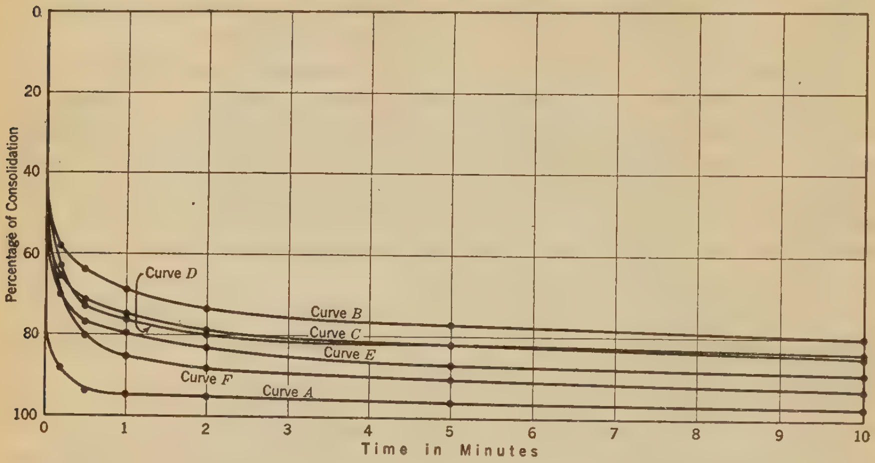

FIG. 30.—CURVES SHOWING RATE OF CONSOLIDATION OF A COBBLE MOUNTAIN DAM CORE SAMPLE.

TABLE 6.—IDENTITY AND DESCRIPTION OF CURVES IN FIG. 30

Curve in Fig. 30	Pressure, in pounds per square inch	Percentage of Voids		Time, in hours, for 100% consolidation
		Initial	Final	
A	8.6	49.6	45.0	20
B	13.0	45.0	44.4	19
C	25.0	44.4	43.2	23
D	50.7	43.2	41.6	21
E	101.5	41.6	39.6	17
F	199.5	39.6	37.6	22

It was clearly stated that the consolidation study was only "an attempt * * * to estimate roughly the time necessary for an approximate ultimate consolidation." So many factors enter into the computation—there are so many assumptions and uncertainties—that it is not worth while to go into too much refinement. The purpose of the study was to determine whether the approximate consolidation would take, say, 2 or 20 years; even if the results obtained for the approximate consolidation vary from those of the actual, say, 100%, or, from 2 to 4 years, the study serves the purpose for which it was made.

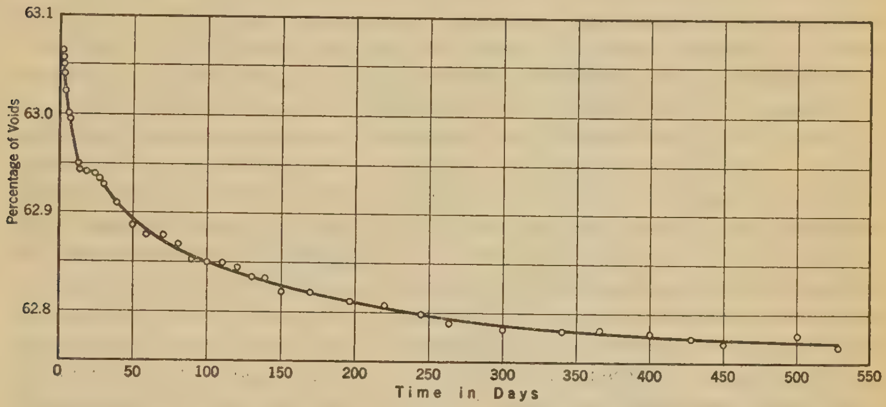

FIG. 31.—COMPRESSION UNDER A STEADY APPLICATION OF LOAD (RE-PLOTTED FROM FIG. 23).

Mr. Cox has computed the time for the consolidation of the Cobble Mountain Dam by Professor Gilboy's method, and the results do not agree with those of Equation (30); but the difference between the results by the two methods is due only to errors in Mr. Cox's computation, or assumed dimensions, rather than to the assumptions, or to the derivation of Equation (30).

"Taking an elliptical cylinder (semi-major axis, 5 930 cm, and semi-minor axis, 4 780 cm) that has an area roughly equivalent to that of the dam core, and a ratio of diameters about that of height to one-half the width of the actual core," as recommended by Mr. Cox, is erroneous and cannot apply to the core of the Cobble Mountain Dam. Far from being "roughly equivalent," the area of an elliptical cylinder with the given dimensions is approximately five times that of the dam core (see Fig. 17). In order to have "a ratio of diameters about that of height to one-half the width of the actual core," the semi-minor axis should have been about one-half the value assumed by Mr. Cox. Applying the dimensions used by Mr. Cox to the Cobble Mountain Dam, or assuming twice the width of the actual core, and without going into any further details, it is seen, in Equation (30), that the time of consolidation varies as the square of the core width; or, in this case, it would be increased four times that given in connection with Equation (30) in the original paper which agrees with the tabular values given by Mr. Cox. It is interesting to note that results by Equation (30) agree so well with those obtained by more complicated and elaborate methods.

The seven reasons given to warn against deceptive conclusions, were pointed out after serious and repeated practical observations. They are still valid, at least for the Cobble Mountain materials, notwithstanding the objections offered by Mr. Cox.

It is not possible, with a few cubic centimeters of material enclosed in a polished brass cylinder, to duplicate the changing conditions and the characteristics of 300 000 cu yd of core material in a dam 263 ft high. There is a practical limit to the possibility of determining the reactions in a large core by means of theoretical laboratory investigations conducted under ideal conditions and with small test samples that are not necessarily representative.

Undoubtedly, much additional research will have to be done, and perhaps new tests and testing methods will be devised in connection with hydraulic-fill construction; but the time has come when engineers connected with this type of construction should get together and co-ordinate the various methods of successful testing and to classify data gathered from successful structures. It is time that engineers should talk the same language and express themselves in the same terms and definitions so that differences in results can be distinguished readily by practising engineers who are not concerned with abstruse theories, the application of which to the problem on hand may yet be somewhat questionable. There is no reason why, until something better is offered, the consensus of opinions and facts compiled by actual experience should not serve as a guide for this type of construction. Establishment of standard tests and testing methods in no way implies that further research should be stopped; on the contrary, the present chaotic condition will be clarified, and much duplication of work will be avoided. Time thus saved can be used for research in the other investigations necessary to a solution of the many features of the problem.

Throughout the paper readers were cautioned against accepting any conclusion as final, and against applying it to another locality in which the materials were different. For a quick decision, or for estimating the probable results during construction, the utility of data obtained from grain sizes and their gradation is paramount until some better and quicker method can be developed. With thousands of yards of material daily going into the structure, there must be some practical means by which the engineer responsible for its safety can readily determine the course to be followed in the control of the construction, if conditions so require. It would be out of the question to stop the construction for weeks at a time in order to determine what should be done.

The writer feels grateful to the discussers, even though some of the views expressed were contrary to those in the paper. After all, however, the difference in opinion will help to bring out the fundamental principles of the subject-matter more definitely than ready acquiescence.

Paper No. 1863

FOUNDATION TREATMENT AT RODRIGUEZ DAM[1]

By Charles P. Williams,[2] M. Am. Soc. C. E.

With Discussion by Messrs. L. A. Robb, Francisco Gomez-Perez, F. A. Noetzli, and Charles P. Williams

Synopsis

This is an account of the design and construction of the foundation structure for the Rodriguez Dam, on the Tijuana River, Baja California, Mexico. The dam is of the Ambursen type, and, as designed, has a greater height than any dam of that type heretofore built. The bed-rock in parts of the stream bed is of inferior quality, and, in some parts, disintegrated. A geologic fault about 20 ft. in width extends along the border of the stream bed.

A brief introductory description of the project and of the dam is given, the geologic formation at the site is described, and the foundation structure that supports that part of the dam which otherwise would rest on poor foundation, is described and illustrated.

Introduction

The Rodriguez Dam is situated on the Tijuana River, in the northern part of Baja California, Mexico, about 11 miles easterly from the Town of Tijuana. Its purpose is the storage and diversion of water for the irrigation of about 5 000 acres in the Tijuana Valley in Mexico, and for domestic supply for the municipality of Tijuana which has a population of 10 000.

The drainage basin of the river, which lies partly in Baja California and partly in San Diego County, California, has an area of 1 670 sq. miles. This is greater than that of any other stream south of Los Angeles, Calif., and west of the Colorado River; it nearly equals the total area of the drainage basins of all other streams in San Diego County. The stream has two principal branches, upon the larger and more southerly of which the Rodriguez Dam has been located. The area of the drainage basin above the Rodriguez site is 938 sq. miles.

---

[1] Presented at the meeting of the Irrigation Division, Sacramento, Calif., April 24, 1930.

[2] Cons. Engr., Los Angeles, Calif.

Like all streams in the vicinity, the flow of the Tijuana River in ordinary years is very small, and the supply is necessarily dependent upon the storage of flood waters. Periods of from 5 to 7 years, in which the flow is insignificant, may be expected, and consequently large carry-over storage is important. In order to furnish a sufficient irrigation and municipal supply from Rodriguez Reservoir, a capacity of about 110 000 acre-ft. is necessary, requiring a maximum reservoir water surface about 180 ft. above the stream bed.

While streams in this vicinity, even during the rainy season, have very small flows in ordinary years, excessive floods sometimes occur. The largest flood of definite record was that of 1916. Some of the streams in San Diego County, at the peak of that flood, had flows corresponding to coefficients ranging from 5 to 7 in Talbot's formula. At that time, the flow of the Tijuana River, below the Arroyo Matanuco, which empties into the river immediately below the Rodriguez Dam site, and which has a drainage area of only 115 sq. miles, was about 70 000 sec-ft. It is estimated, however, that a flood of 150 000 sec-ft. is possible.

The Rodriguez site is in a gorge which, at its narrowest section, has a width at stream bed of about 100 ft.; at 130 ft. above stream bed, the width is about 750 ft. Beyond this, on either side, the gorge is flanked by a saddle and by gentle slopes which, immediately adjacent to the site, rise to 200 ft., or more, above stream bed.

Rock outcrops throughout a considerable portion of the site, the rock of the canyon walls at the gorge, that of the western slope, and that of a part of the eastern slope being rhyolite, while that of the easterly part of the eastern slope is granite. The rock is fused at the contact between the granite and the rhyolite, showing the latter to be the older rock, and indicating that no great leakage from the reservoir may be expected along the contact. The surface rock of the canyon walls, in the narrowest section, is fresh and hard, although considerably broken; that of the slopes is generally badly weathered, and, in some parts, considerably disintegrated. On either side of the canyon, are a number of cleavage planes which dip toward the stream bed and, in some cases, up stream.

PRELIMINARY INVESTIGATIONS

In the preliminary investigation of the dam site, nine borings were made in the stream bed and fifty-two test pits were excavated on the side hills. The latter indicated that suitable rock for foundation could be secured, ordinarily, with comparatively shallow excavation. At the site of the east wing of the dam, for a distance of about 500 ft., suitable rock was found at depths ranging from 15 to 25 ft., while at the site of the proposed spillway, on the west side of the river, the depth for about 100 ft. was from 15 to 40 ft. Five of the nine borings in the stream bed indicated satisfactory rock at depths not exceeding 50 ft. From four of the borings, no cores could be obtained, the borings being made easily with a chopping bit. The materials obtained from two of these four borings were clean sharp stone chips, but the materials from the other two gave considerable evidence of disintegration.

After the borings had been made and a number of the test pits had been excavated, the geological formation at the site and in the vicinity, both in Mexico and in the United States, was examined by a geologist, who reported that, in his opinion, the rock in the stream bed, that of the western flank, and that of a part of the eastern flank, would be found suitable for a foundation for a concrete dam, but that he considered an earth and rock-fill dam to be best suited for the saddle on the eastern flank.

Brief Description of the Dam

The dam is of the Ambursen type. Its maximum planned height is 187 ft. above the stream bed and about 240 ft. above the lowest foundation bed-rock. The length of the crest is about 2 000 ft. For the central part of the dam and for the west wing, the spacing of the buttresses is 22 ft., center to center. The buttresses for the central part and the west wing vary in thickness from 19 in. at their thinnest section, to 66 in. at 200 ft. below the crest. The thickness of the deck varies from 25 in. at 15 ft. below the crest to 64.5 in. at its lowest portion, 192 ft. below the crest. The lower face of the deck has a slope of 1 on 1, and the down-stream face of the buttresses a batter of 5 on 1.

In each of three of the stream-bed bays of the dam, the plans provide for a 5 by 5-ft. sliding sluice-gate, operated by a hydraulic cylinder. The service outlet works consist of two 30-in. cast-iron pipes, at an elevation about 33 ft. above the stream bed, in each of which will be installed one 30 by 24-in. needle-valve, and two 30-in. emergency gate-valves. The discharge will be measured by a Venturi meter.

The spillway in the west wing of the dam is to be controlled by nine 30 by 30-ft. structural steel gates on caterpillar bearings. With an elevation of the water surface 6.5 ft. below the crest of the dam, the spillway is designed for an estimated capacity of 150 000 sec-ft.

The Foundation

On February 17, 1928, Gen. Abelardo L. Rodriguez, Governor of the Northern District of Baja California, entered into a contract with the Ambursen Dam Company for the design and construction of a dam at the Rodriguez site, to be subject to the approval of the Government.

Excavation in the stream bed was begun by sub-contractors on May 21, 1928. In August, bed-rock was encountered at several points near the up-stream limit of the excavation, at about 35 ft. below the original elevation of the stream bed. The rock was much broken and not suitable for buttress foundations. A geologic fault, about 20 ft. in width in the exposed portion, which extended in a direction nearly parallel to the stream bed along its eastern margin, and which had not been indicated by surface conditions, was revealed by the excavation. The excavation for the cut-off wall, begun in August, disclosed badly disintegrated rock in mid-stream.

Early in September, Dr. F. L. Ransome, Consulting Geologist, Dr. Paul Waitz, Consulting Geologist for the National Commission of Irrigation, of Mexico, and the late A. J. Wiley, M. Am. Soc. C. E., were called for consultation regarding the conditions affecting the suitability of the site for the construction of a dam of the type proposed. The problems to be considered were the possibility of excessive leakage from the reservoir, the practicability of obtaining adequate foundation for the dam, the probable depth and extent of cut-off wall required, and the possible danger of future seismic disturbance. A further inspection was made by Messrs. Wiley and Ransome on November 11 to 13, 1928, at which time the cut-off trench had been excavated to a depth of about 33 ft. below the bed-rock surface.

FIG. 1.—RODRIGUEZ DAM: LONGITUDINAL SECTION OF CUT-OFF TRENCH IN STREAM BED.

After this inspection, Dr. Ransome reiterated his opinion as reported previously under date of September 13, 1928. In the report mentioned it was pointed out that the site chosen was satisfactory in most respects. One grave defect, however, was the existence of a fault zone which, although it had been inactive for more than 100 years, might conceivably move in the future. Nevertheless, such movement is not expected and Dr. Ransome stated that the risk was not so great as to justify the condemnation of the site.

A longitudinal section of the cut-off trench in the stream bed, showing the formation disclosed at the time of Dr. Ransome's inspection, is shown by Fig. 1. The general character of the rock in the stream bed is shown by Fig. 2.

The bearing power of the rock in the stream bed varies greatly in different parts of the foundation area. Four of the buttresses, if founded on the natural material, would rest for a part of their lengths upon material of relatively poor bearing power. The easterly two of the four would be founded for part of their lengths upon the material of the main fault. It was realized, therefore, that it would be necessary to support the four buttresses by a structure of a type such that the loads from the weaker parts of the foundation area would be transferred to those parts having ample supporting power.

After a number of preliminary studies had been made a design was submitted providing for a reinforced concrete floor, 8 ft. thick, covering the entire stream bed within the foundation area. Above, and tied to the floor by steel reinforcement, were massive reinforced concrete ribs, 5 ft. thick and spaced 20 ft., center to center. These ribs were designed so as to transfer the buttress loads, by internal arch action, to the sound rock on either side of the stream bed. The internal arches were defined within the ribs by means of bands of reinforcing steel which were extended through the buttresses, the buttresses and ribs forming a cellular structure. Besides serving as a support for the buttresses, the ribs were intended to serve as horizontal bracing for the rock of the canyon walls, which was cut by a number of cleavage planes sloping toward the stream bed.

FIG. 2.—CHARACTER OF FOUNDATION ROCK IN RIVER CHANNEL.

The design was reviewed by the late Fred A. Noetzli, M. Am. Soc. C. E., and was found sufficient for the purpose for which it was intended. Later, it was considered by a Consulting Board consisting of Messrs. Wiley, Noetzli, and the writer, assisted by Spencer W. Stewart, M. Am. Soc. C. E., which Board concluded that while the proposed structure had been found by analysis to be reasonably sufficient, a more satisfactory and only a little more costly structure would be obtained by building a voussoir concrete arch, continuous from the up-stream cut-off wall to the toe of the dam, with a curved extrados and a flat base, resting on the natural material. It was proposed that the arch consist of unreinforced massive voussoir blocks with staggered radial joints, each block extending, without construction joints, from the base to the extrados.

In designing the structure the upper part was to be considered an arch, with the theoretical intrados intersecting the canyon walls above the lower limit of sound rock. It was to be assumed that the load of the concrete below the theoretical intrados would be carried by the natural foundation material, and that the arch would support only the buttress loading with reservoir water surface at the elevation of assumed high water, the weight of the arch above the theoretical intrados, and the water load between the buttresses to the elevation of assumed low water below the dam. Since the structure was assumed to be fully submerged at all times, stresses due to variations in temperature were to be neglected. Uplift under the structure, due to low-water pressure, was to be assumed. Further consideration of the problem led to the adoption of a definite construction joint at the intrados.

On account of the importance of the problem, independent designs were prepared by Mr. Noetzli and the contractor. These were considered by a board consisting of Messrs. Wiley and Noetzli, C. V. Davis, Assoc. M. Am. Soc. C. E., and the writer, and final conclusions were reached regarding the type of structure and important details.

The essential features of the adopted design are shown by Figs. 3 and 4. From Fig. 3 it will be observed that the four buttresses, *B* East, *A* East, *A* West, and *B* West, are supported by the arch. In order, in so far as possible, to avoid undesirable twisting moments in the arch barrel and irregular deflection along the line of support of any buttress, the axial line of the arch crown was made parallel to and equi-distant from the center lines of the buttresses, *A* East and *A* West. This made it necessary, at some sections, to use arch spans of greater length than would have been required to span the fault and the rock of inferior quality. On account of the varying widths to be spanned, and of the non-uniform loading, it was necessary to use arches of greater rise at the up-stream and down-stream parts of the structure, than in the central part, as shown by Fig. 4.

FIG. 3.—TYPICAL SECTION OF FINAL DESIGN, SHOWING TRANSITION, RODRIGUEZ DAM.

The arch is designed to carry the full superimposed load. It is expected, however, that a considerable part of the load will be supported through the sub-intradosal concrete by the natural material in the stream bed. Where, however, such material has not supporting power sufficient for the entire load and there is incipient settlement, a part of the load will be taken by the arch, thus relieving the natural material of as much of this load as may be necessary to prevent further settlement.

Before beginning the construction of the sub-intradosal concrete blocks, cut-off trenches about 3 ft. deep, 2 ft. wide, and spaced 25 ft., center to center, were cut across the stream bed, in the fault zone, and where the rock was of inferior quality. The stream bed was then covered with a concrete mat, not less than 2 ft. in thickness. Substantial key-ways, to prevent sliding, were constructed in the upper surface of the mat.

FIG. 4.—TYPICAL SECTION THROUGH BUTTRESS, RODRIGUEZ DAM.

The sub-intradosal concrete was constructed of inter-locking blocks, as shown in Fig. 3. The upper surfaces of the blocks, upon which the arch barrel rests, were finished smooth and painted with oil to prevent adhesion. Transverse keys about 6 in. deep and 10 ft. wide, were constructed in the sub-intradosal blocks in order to prevent sliding of one course upon another, or sliding of the arch upon the blocks.

Normally, the water pressure under the arch will be that due to low water below the dam. During a flood, the water below the dam might rise within a short time to 15 ft., or more, above low water. This, coming at a time when the reservoir would be full, would impose a heavy load upon the arch, unless provision was made for equalizing the pressures upon the extrados and the intrados. To accomplish this, water-inlet grooves were constructed the entire length of the arch, with 2-in. inlet pipes at 15-ft. and 20-ft. intervals. It was first intended that these grooves should be filled with screened gravel, ranging in size from ¼ in. to ¾ in., the gravel to be covered by a layer of porous mortar. Owing to some of the grooves being on steeply sloping surfaces, it was found very difficult to retain this type of filling in place. The grooves were filled, therefore, with pre-cast blocks of mortar, consisting of 1 part cement to 10 parts of coarse manufactured sand. These blocks were so porous as to offer very little resistance to the passage of water. After being placed in the grooves, they were covered with a coat of mortar consisting of 1 part cement and 3 parts river sand.

Between the haunches of the arch and the walls of the canyon, concrete filling was placed to varying heights, depending upon the apparent stability of the rock walls. Above this filling and above the extrados of the arch, concrete walls 5 ft. thick, spaced generally 20 ft., center to center, have been constructed to the elevation of the stream bed, these walls, as well as the haunch filling, being for the purpose of bracing the side walls of the canyon, as a preventive of possible sliding on planes of cleavage.

In order that it may be possible at any time to determine the upward water pressure at various points at the base of the foundation structure, thirty-five 4-in., galvanized and dipped pipes have been placed in the structure, leading from the points at which the uplift pressure is to be measured, a few feet upward, then horizontally to four centralized points, from which they continue vertically upward through the structure. Eventually, the pipes will be extended vertically upward to observation platforms above high water below the dam. The lower end of each vertical riser will be always below the hydraulic grade at the point where the pressure is measured. The pressure is determined by observing the elevation of the water surface in the riser pipes, or by a pressure gauge, if, in any case, the elevation of the hydraulic grade at the point to be measured is higher than the top of the riser pipe. The plan of the pipe system is shown by Fig. 5.

Fig. 5.—Plan Showing Location of Riser Pipes for Foundation Testing System, Rodriguez Dam.

The arch barrel resembles a frame type of structure, which was adopted as the most suitable because of the large concentrated buttress loads. The stresses were computed by the elastic theory. The procedure followed in designing the several theoretical sections of the arch barrel was, as follows: Having determined the thickness and other dimensions of the arch rib by trial computations at a given section of the arch barrel (on the basis of its span and rise), the pressure line for the loads and weights was drawn and the arch axis made to coincide with this pressure line. The direct compression stresses at the crown and at the abutment could then readily be computed. The stresses due to rib-shortening, shear, and temperature variations were then calculated by the method of least work. These stresses, added algebraically to the direct compression stresses, gave the maximum and minimum stresses at the crown and at the abutments. The half section of the arch was divided into ten hypothetical voussoirs, and the stresses were computed at each voussoir point.

The working loads adopted for the arch-barrel designs were, for maximum compression, 700 lb. per sq. in., and for maximum tension, 50 lb. per sq. in. The final designs showed no tension in any arch section and no reinforcement was used.

The intended minimum compressive strength of concrete at 28 days, adopted for the mat, for the arch barrel, and for the 5-ft. bracing walls, was 2 000 lb. per sq. in., and that for the sub-intradosal concrete and the haunch filling, 1 200 lb. per sq. in. At the beginning of construction, the volumes of materials used per batch, in making concrete of the intended strength of 2 000 lb. per sq. in. at 28 days, were as follows:

Cement	8 sacks
Sand	18.3 cu. ft.
Gravel:	
$\frac{5}{16}$ to $1\frac{3}{4}$-in.	13.8 cu. ft.
$1\frac{3}{4}$ to $3\frac{1}{2}$-in.	13.8 cu. ft., or 24.0 cu. ft.
$3\frac{1}{2}$ to 6-in.	13.8 cu. ft.
Water-cement ratio	1.0

Afterward, it became evident that the desired strength could be obtained with a greater water-cement ratio, and the ratio was increased to 1.08. The use of the greater ratio made it possible to reduce the quantity of cement per batch to 7 sacks without reducing the workability appreciably. In the concrete for the sub-intradosal blocks, the volumes of materials per batch first used were: 6 sacks of cement and a water-cement ratio of 1.25. The sand and gravel quantities were the same as for the 2 000-lb. concrete. The number of sacks of cement per batch was reduced afterward to $5\frac{1}{2}$, with no change in the water-cement ratio.

The design of the transition structure between the flexible arch barrel and the rigid cut-off wall was a problem of some difficulty. The transition is shown in cross-section by Fig. 4. It consists of a massive block of concrete having a vertical depth ranging from 40 to 50 ft. and spanning the entire stream bed. The block overlaps the cut-off wall and is tied by steel reinforcement to the arch barrel. The bottom is reinforced longitudinally with three layers of $1\frac{1}{2}$-in. square steel bars, spaced 12 in., center to center, to resist possible tension due to bending in areas where the natural foundation has insufficient supporting power. It is reinforced at its easterly end by seven courses of $1\frac{1}{8}$-in. square diagonal tension bars, spaced 24 in., center to center, to aid in carrying the load at the fault to the solid rock on the eastern bank. It is also reinforced for possible diagonal tension due to its support by the cut-off wall.

CUT-OFF WALL

When the fault in the stream bed was discovered, it was realized that it would be necessary to carry the cut-off wall at the fault to a great depth. There was considerable doubt, however, regarding the depth to which it would be necessary to construct the wall in the western portion of the stream bed.

FIG. 6.—CUT-OFF WALL, PLAN AND LONGITUDINAL SECTION AT RIVER CHANNEL, RODRIGUEZ DAM.

Excavation of the cut-off trench was begun in open cut and was carried by this method to a depth of from 26 to 33 ft. below the original rock surface, corresponding to depths of from 66 to 72 ft. below the stream bed. The greater part of the trench required timbering. When the depths mentioned had been reached, maintaining the open cut had become so difficult that a change of method was necessary, and it was decided to continue the excavation through shafts. The trench was filled with concrete, in which ten shafts were constructed, through which the excavation and the placing of concrete were continued. The shafts are shown in plan and section by Fig. 6. The walls of the shafts were reinforced throughout the zone of inferior rock and well into the solid rock on either side. Stop-water key-ways were constructed in the walls, and, when excavation shall have been completed, the shafts will be filled with concrete or puddle, as then may be considered desirable.

Numerous grout pipes were inserted in the shaft walls, where the rock was broken or seamy, and two lines of grout holes, staggered in two rows 5 ft. apart, and spaced not exceeding 10 ft. apart in each row, were drilled from the bottoms of the shafts throughout that part of the length of the wall, where final depth has been reached. It is planned to drill numerous grout holes adjacent to and eastward from the fault, along the line of the cut-off wall extended, where the rock, although hard, is more or less broken.

Provision was made for the installation of twelve pressure pipes for determining the hydraulic gradient at various points on the up-stream and down-stream faces of the cut-off wall.

The length of wall constructed through shafts was, at the beginning, about 150 ft. At a depth of about 66 ft. below the original rock surface, the length had decreased to about 110 ft. Excavation and concrete shaft-walls have been carried to a depth of about 112 ft. below the original rock surface, or 150 ft. below stream bed, at which depth the length is about 90 ft. It is intended to carry the wall at the fault, and as far on either side as may be found necessary to secure a key in suitable rock, to a depth of 300 ft. below stream bed.

DISCUSSION

L. A. Robb,[8] M. Am. Soc. C. E. (by letter).—The foundation arch, the side-hill bracing walls, and the deep cellular-wedge type of cut-off wall of the structure described by Mr. Williams in his timely and interesting paper are innovations in dam design that may have a far-reaching effect. Faulted foundations and broken-rock banks, such as have been discussed by the author, will be encountered more frequently in the future because sites consisting entirely of sound rock are becoming increasingly scarce; and yet the development of these faulted and otherwise unsatisfactory sites are frequently of great economic importance.

Certain principles of foundation design and construction as presented by the author, with modifications, may be applied broadly to other difficult foundation problems of a similar nature. Aside from foundations which uniformly have low bearing value, such as clay or sand, difficulties are more frequently being encountered with: First, those foundations in which there exist the danger of horizontal or inclined movement, owing to seams and planes of cleavage; and, second, foundations consisting of materials varying widely in bearing value.

In the first type, movement may occur from earth or rock slides in the bank, due to planes of cleavage in the foundation material, or from more or

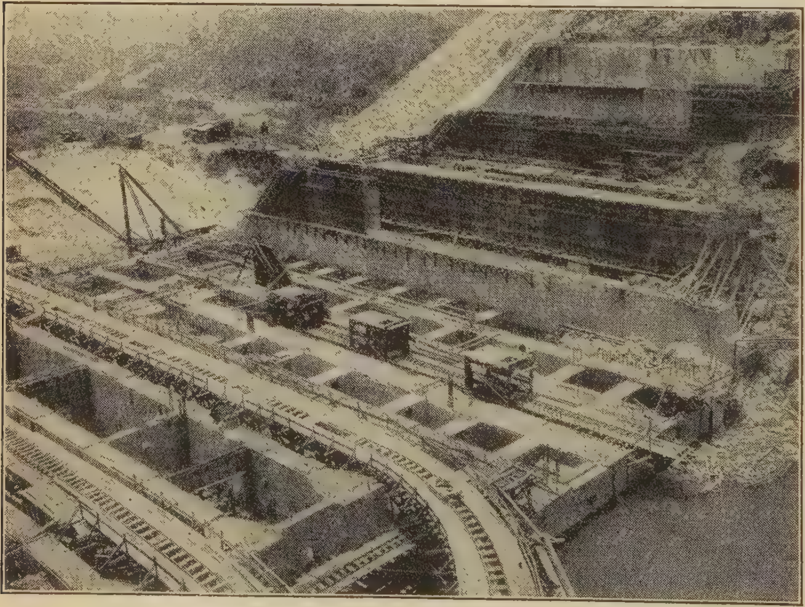

Fig. 7.—View Southwest from No. 2 Concrete Plant.

---

[8] Vice-Pres., Ambursen Construction Co., New York, N. Y.

less horizontal planes of cleavage in the rock below the dam foundations. Such movements caused the failures of large gravity dams at both Austin, Pa., and Austin, Tex.[4]

Foundations of this type require that the seamed rock banks be braced either across the valley or anchored firmly to sound rock below in such a manner that the seams are water-tight and that lateral or longitudinal movements will be impossible. At the Rodriguez Dam the method of bracing the seamed rocks across the valley was used, as shown by Fig. 7.

Similar shattered bank conditions were encountered at another site recently studied. However, in this case, the valley was too wide to use bracing ribs. In addition, this problem was complicated by the fact that the side hills were of such height that loosened or broken material would have made excavation extremely hazardous. A foundation structure, involving a modification of the cellular-wedge cut-off construction described by the author, was worked out as a possible solution for this problem.

Fig. 8 shows the suggested design. It was proposed to construct four lines of the cellular-wedge type of cut-off walls, starting in the river bed and working upwardly into the bank. It was also proposed to carry the foundations of these walls well into sound rock and to converge the four lines as shown by Fig. 8 so that the up-stream and down-stream walls would coincide with the heel and toe of the dam. The footings are designed as an integral part of these walls, creating in effect a large subterranean reinforced concrete frame which would be capable at conservative stresses of carrying any possible thrust from the shattered or seamed side hill to the sound rock in the river bed below, and, in addition, would firmly anchor the dam to a sound foundation throughout its entire structure.

A foundation structure of this type could be constructed safely because a dangerous slide would be prevented during construction by the bracing action of the struts. No shoring or expensive bracing is required, and only a small amount of unsupported excavation is exposed at one time.

Several modifications of the arch-barrel design described by the author may be used in a treatment of foundations having widely different bearing values. It is necessary in such cases to span the areas of poor foundation with structural members that are supported by sound rock on each side, such as was the case for the Rodriguez Dam. An alternate type of structure, such as Fig. 9, might be used to advantage in other projects.

This type consists of an arch barrel or frame supporting the buttresses. Directly below the buttresses are heavy piers which, in turn, rest on a massive concrete mat spreading over the poor foundation material. This mat acts as a chord member to the arch and piers creating in effect a Vierendeel truss. The arch barrel is capable of taking all loads from the dam and the reservoir above. However, under normal conditions, the poor foundation material will actually take a substantial part of the load. The merits of such a structure are substantially the same as those of the type described by Mr. Williams.

The type of cut-off wall adopted for the Rodriguez Dam was also used in connection with the construction of a 30-ft addition of height to the Bristol

Fig. 8.

Dam on the Pemigewasset River, near Bristol, N. H. At the east bank of this dam ledge rock slopes away from the ground line instead of following the more usual course of sloping in the general direction of the earth contours above. In order to provide adequate resistance against percolation through this bank a cut-off wall was required which increased in depth as the wall is carried into the bank, until the foundation of the wall was in ledge rock about 110 ft below the ground surface.

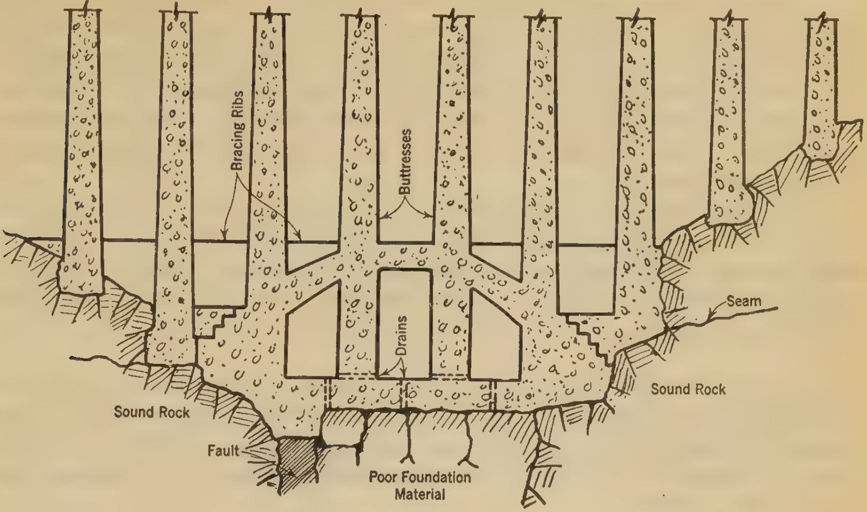

FIG. 9.

The concrete cut-off for the Bristol Dam was carried down through clay, gravel, and boulders, at the rate of about 1 ft in depth per day. Provisions were made to grout the joints between the sections of wall. The grout pipes also served as drains for the purpose of relieving hydrostatic pressure during construction. The advantages of using this type of wall are, as follows:

1.—The necessity of excavating a wide, deep trench and of using expensive and dangerous shoring is avoided.

2.—Wedge action firmly compacts the material supporting the wall and thus greatly increases the resistance of the wall to water travel.

3.—This procedure offers a safe and rapid method of constructing a deep cut-off wall and involves a minimum amount of exposed excavation.

4.—The wall is not endangered by flood hazards while it is in process of construction. If in the river bed, during the flood season, the cellular spaces may easily be protected against filling with silt and débris and only a minimum amount of pumping will be required to empty the cells after the flood has passed, or the shafts may be carried up above flood-water level and construction continued uninterruptedly.

FRANCISCO GOMEZ-PEREZ,[5] JUN. AM. SOC. C. E. (by letter).—In his paper the author has covered his subject in so thorough and complete a manner that it is difficult to add anything without having to enter into other phases of the construction which are independent of the foundation and, therefore, not within the scope of the discussion.

---

[5] With Mexican National Irrig. Comm., City of Mexico, Mexico.

A point of view implied in the paper but which, because it is not of a technical nature, is not developed, brings attention to the fact that even in the face of difficulties of various kinds, Mexico is doing what she can to proceed with the construction of public works. These include some of National scope, such as irrigation developments, in which members of the Society have co-operated. The technical aspects of some of these projects have been published by the Society.

It is to be hoped that the association of engineers from the United States, endowed with such a high technical and cultural background, and such personal integrity, with Mexican engineers, will tend toward mutual understanding and appreciation, which, in time, will bring about a more cordial and effective co-operation.

F. A. Noetzli,[6] M. Am. Soc. C. E. (by letter).—The unusual foundation conditions at Rodriguez Dam, which involve a geologic fault about 20 ft wide, presented a problem that could be met only by unusual methods. Mr. Williams has presented a clear and concise description of how the difficulties were successfully overcome.

The main feature of the foundation structure is a horizontal foundation arch that bridges the bottom of the canyon with a clear span of, roughly, 70 ft and extends for a distance of approximately 250 ft in an up-stream and down-stream direction. This long arch barrel supports four of the highest buttresses of the dam.

At first, the problem of the design of a foundation arch for supporting buttresses nearly 250 ft long, seemed to present almost insurmountable difficulties from a theoretical point of view, mainly because of the necessity of taking into account the arch deflections resulting from the heavy concentrated loads exerted by the buttresses.

The foundation arch had to meet the following requirements: (*a*) The axis of the arch barrel was to be parallel to the buttresses so as to avoid undesirable twisting moments; (*b*) the span, radius, and thickness of the elementary arches of the arch barrel were to be of such a size that the theoretical arch deflections along the base of each buttress would be as nearly as practicable on a straight line and would correspond to the trapezoidal stress at the base of the buttresses.

Fortunately, the bed-rock conditions along both side hills at the bottom of the canyon made it possible to meet these requirements very closely. For some parts of the arch barrel it was necessary to use arch spans of greater length than would have been necessary to span the fault and the rock of inferior quality, and, for certain other parts, some extra excavation was required; but, in general, the conditions may be said to have been rather favorable for a foundation structure of the type adopted.

---

[6] Cons. Hydr. Engr., Los Angeles, Calif. Mr. Noetzli died on May 24, 1933.

The structural analysis of the individual elementary arches was made by the elastic theory and offered no unusual difficulties. For the purpose of design the arch barrel was divided into strips from 10 to 20 ft long. The radius, span, and central angle, and the thickness of each strip at crown and abutment were then determined by "cut and trial" such that the necessary conditions regarding deflections and permissible maximum unit stresses were met within reasonably close limits. It is of importance to note that the buttress walls that transmit the load to the foundation arch are relatively stiff in a vertical direction. They will tend, therefore, to force a practically linear deflection of the foundation barrel to occur along the base of each buttress, regardless of the results of the theoretical analysis. For small differences between theoretical and actual straight-line deflections the loads on the individual strips will depend upon their relative stiffness, such that the stiffer parts will carry somewhat more than the theoretical load, but will thereby relieve the relatively more flexible parts by the same amount of load. For instance, if one strip of the arch barrel were overloaded by, say, 5% of its theoretical load, the adjoining strip or strips would be relieved by approximately this same amount so that under actual load conditions the deflections of the arch barrel would again vary practically linearly along the base of each buttress. For safety, the lower part of each buttress is strongly reinforced, as shown in the author's Fig. 3.

While the foundation arch is designed to carry the full superimposed load, no doubt a considerable part of this load will be supported through the subintradosal concrete by the natural foundation material in the bottom of the canyon.

Small irregularities in settlements of one buttress relative to the others are not likely to affect the stability of the dam, because of the relative flexibility of this type of structure.

One interesting feature of the foundation structure of the Rodriguez Dam is the provision for admitting water through inlet pipes along the intrados of the foundation arch, whereby artificial uplift pressure is created which, in periods of floods, counteracts the heavy load on the foundation arch, due to back-water entering between the buttresses.

Charles P. Williams,[7] M. Am. Soc. C. E. (by letter).—In view of the somewhat radical departure from conventional types of foundations for buttressed dams, the writer would have appreciated a more critical discussion by those who heard, or have read, the paper and have viewed the work during construction. Nevertheless, he appreciates the comments of those who entered into the discussion.

The building of any storage dam is a serious responsibility, especially in a region subject to earthquakes and at a site traversed by a geologic fault. The construction at such a site necessarily involves some risk. However, the region around the Rodriguez Dam is dependent absolutely upon storage for its water supply. Ground storage sufficient to meet the requirement cannot be developed. Periods of five years in which there is no stream flow are of common occurrence. Records show one period of seven years during which the run-off was insignificant. The construction of reservoirs at the best, or at the least objectionable, sites is a necessity. The question is whether the risk is too great to justify continued development and, if not, what type of structure shall be built in order to secure the greatest practicable insurance against damage.

---

[7] Cons. Engr., Los Angeles, Calif.

No comment on the discussions submitted appears to be necessary. At the time of the presentation of the paper at the meeting of the Irrigation Division, in Sacramento, Calif., in April, 1930, some comment was presented relative to the geology of the site. It was suggested that the rift in the bedrock at the Rodriguez site is not a true fault, but a tensile crack, the main fault lying between the mainland and the Coronado Islands; that the type of dam selected is not suited to the site; and that a more flexible type, such as an earth or rock-fill dam, should have been chosen.

The fact that the rift at the dam site is a true fault, and not a mere tensile crack, is proved by the occurrence of dense clay gouge, as much as 1 ft thick, along the faces of the hanging wall and foot wall.

At the time of the preliminary examination, the writer suggested an earth and rock-fill dam as being the type probably best suited to the site. This recommendation was made without knowledge of the existence of a fault, but with the knowledge that borings indicated, for a part of the foundation area in the stream bed, underlying disintegrated material extending to a depth of more than 100 ft. The writer had no part in the selection of the type of dam which eventually was chosen; however, in the light of subsequent determination of the character of the foundation site, he is of the opinion that the selection was fortunate. Excavation disclosed the fault, not discovered in the preceding geological examination. The question of shearing movement along the fault then became one of paramount consideration.

The two geologists who examined the site, after the discovery of the fault, agreed that subsequent movement along the fault is not probable, although it is a possibility. If, then, a dam is to be built at such a site, the question arises as to the type of structure which will restrict the damage to the least possible amount should geologic movement occur. Such a movement might be either a vertical or a horizontal slip, or it might be a separation of the fault walls, forming a crack.

The effect of the earthquake of 1906 on the San Andreas and Upper Crystal Springs (earth) Dams, near San Francisco, Calif., is sometimes cited as evidence of the relative safety of earth dams from damage by seismic disturbance.[8] At the time of the 1906 earthquake, the San Andreas Dam, which then had a maximum height of 95 ft above the stream bed, consisted actually of two dams, separated by a hard narrow ridge through which passes the San Andreas fault. A horizontal slip of about 8 ft occurred at the dam, but this slip was along the fault and did not pass through either of the dams. The structures were somewhat cracked by the earthquake, but failure did not occur although the reservoir was full at the time. The results would have been very different, however, had the slip passed through the dam proper. The Upper Crystal Springs Dam, having a maximum height of 85 ft above the stream bed, is crossed by the San Andreas fault. At the time of the 1906 earthquake, there was a horizontal slip of 8 ft through the body of the dam. This dam lies between the Upper and the Lower Crystal Springs Reservoirs and, at the time of the earthquake, the water stood at the same elevation above and below the dam. Very different results might have been expected, if the dam had been subject to unbalanced hydrostatic pressure.

---

[8] *Engineering News-Record,* August 25, 1932, p. 218, and September 29, 1932, p. 385.

It is inconceivable that a slip, such as occurred at the San Andreas and Upper Crystal Springs Dams, could occur in an earth dam of the height of the Rodriguez Dam, with a large quantity of water in storage, without failure resulting from the admission of water into the body of the dam through cracks, or, possibly, in the case of a vertical slip, by overtopping. After initial failure, progressive failure would be rapid, resulting in early collapse. The objection to an earth dam, at this site, applies, in a somewhat less degree, to a rock-fill dam.

The Ambursen type of dam is more flexible than any other type of concrete dam, and small relative movements can occur without resulting in serious torsional stresses. If, however, a slip along the fault should occur, there is possibility of local failure. The failure of one or two buttresses might occur, without affecting seriously the remainder of the structure, except by progressive undermining, which probably would be slow. The dam might be even torn apart, but the separated sections, not being dependent for stability on the part destroyed, would still stand and would retard to a considerable extent the escaping water.

Paper No. 1864

A HISTORY OF THE DEVELOPMENT OF WOODEN BRIDGES

By Robert Fletcher,[1] and J. P. Snow,[2] Members Am. Soc. C. E.

With Discussion by Messrs. Henry B. Seaman, Jasper O. Draffin, E. K. Morse, John W. Storrs, C. J. Hogue, William A. Oliver, Philip G. Laurson, Richard S. Kirby, Wells N. Thompson, Benjamin Wilder Guppy, Ivan E. Houk, William H. Baker, Jr., Oren Reed, R. P. Davis and L. L. Jemison, Peter T. Landsem, J. K. Finch, A. A. Eremin, Aksel Anderson, William G. Atwood, H. Fugl Meyer, W. E. Howland, Harry K. Ellis, Nelson J. Bell, and Robert Fletcher and J. P. Snow.

Synopsis

This story of wooden bridges is written from the engineer's viewpoint. Other writers have presented the æsthetic, non-technical, and sentimental aspect of the subject. Beginning with the dawn of history, the story ends with the evolution of types of timber bridges accomplished only within the two centuries just past; and this development has culminated in the United States, giving to this country the latest types designed in conformity with correct principles and built at minimum cost. In the treatment of the subject three periods may be recognized.

The first period covers what it is now possible to learn concerning wooden bridges constructed by so-called "ancient" people and includes the indefinite period indicated by the historian's phrase, "the fall of the Roman Empire." There seems to be reason for the opinion that types of primitive bridges have survived many centuries in the "unchanging East," and only recently have come distinctly to the knowledge of the Western civilized world. Descriptions of such types are given.

Note.—Published in November, 1932, *Proceedings.*

[1] Director Emeritus, Thayer School of Civ. Eng., Dartmouth Coll., Hanover, N. H.

[2] Cons. Engr., Boston, Mass. Mr. Snow died September 4, 1933.

The second period covers the development in Europe from the so-called "Dark Ages" to about the Sixteenth Century, when scientific knowledge began to influence the minds of mankind—the period of the Renaissance. Then, beginning about the middle of the Eighteenth Century, a variety of types appeared, showing much ingenuity in design and skill in construction. It was a time when both rulers and people gave more attention to public works of all descriptions.

Finally, the modern period deals at greater length with the various stages of development through experimental types of American timber bridges to types now accepted as standard. Such are principally those which make use of lattice, Howe, and Pratt forms of truss, with or without a timber arch in combination.

Presumably the end of the period would be when steel and concrete have displaced timber in bridge construction; but it will appear that, where timber is plentiful and considerations of economy and rapid accomplishment prevail, wooden bridges still have "a reason to be." A review of the dominant facts established is given in the "Summary."

INTRODUCTION

Extensive inquiries made in twenty-four (only one-half) of the United States (Eastern, Middle, Southern, and Central) have revealed the surprising fact that, as late as 1930, there were between 450 and 500 covered bridges in use, a goodly number of which are likely to serve for some decades to come. A quarto volume, published in 1931, gives 135 illustrations of such bridges.[3] The ultimate settlement of a large area of undeveloped country, such as Alaska, South America, and parts of the Eastern Hemisphere, where timber is abundant, will make demands for bridges that can be built with timber, quickly and cheaply, and that will be durable enough for the pioneer period.

Originally, much of the area of the United States was heavily forested, especially the Eastern part. Naturally the first settlers used the timber at hand for bridges and other construction. The shipyards along the New England Coast, where so many fine ships were built, were effective training schools for heavy timber framing; and the influence of that training still remains among the carpenters of the region. Those conditions led to the building of many bridges of note during the period of development and trade after the Revolutionary War. The spirit of emulation and invention which is characteristic of the American people resulted in a flood of patents for bridge-truss types, a few of which have led to good designs which have been widely approved and adopted. The full text of the investigation upon which this paper was based has been placed on file with Engineering Societies Library, in New York, N. Y., to serve as a possible aid to any subsequent research on this point.

---

[3] "Covered Bridges in America," by Rosalie Wells, with foreword by Charles S. Whitney, M. Am. Soc. C. E., New York, William Edwin Rudge, 1931.

The Ancient Background

Undoubtedly the prehistoric man built his bridges with the adaptable materials within his environment. Where trees abounded, a log fallen or felled so as to bridge a stream, would be a suggestion to the most primitive intelligence. Hence, the simple beam bridge, under favoring conditions, would be a first resort and, from prehistoric time to the present, may be regarded as a world-wide type.

Again, if the tale[4] of an early explorer in South America may be believed, even the monkey may have taught the prehistoric man. In a tropical forest he may have seen a chain of monkeys, their bodies locked together by means of their long arms and long tails, hanging from the branch of a tall tree and swaying until the lowermost grabbed a branch on the other side of a stream. Then the crossing of the group on this living bridge, the shifting of the point of attachment on that side, the reverse swing of the chain until the rearmost monkey landed, and, finally, the breaking of the chain would be quite an effective demonstration, if and when witnessed.

In the sub-tropical parts of Central Asia, claimed to be the cradle of the human race, bountiful Nature provided ample material for constructing suspension bridges. There is the rattan, or climbing palm, a species of the *genus calamus,* remarkable for the length of its stems growing out from a slender trunk.[5] These stems are very tough, having hooks by which they climb over bushes and trees; sometimes they attain a length of 300 to 800 ft., or more.

Another adaptable material is found in the liana, defined as any perennial plant having woody stems, which are characteristic of certain geographical regions, as the forests of the Amazon, the jungles of India, etc.[6] In the temperate zone the grapevine is an analogous example. The grass rope is a species of bamboo that belongs to the great grass family.

Rope bridges may be classified into five types: (1) Tight rope; (2) single rope and dragline; (3) toboggan; (4) roadway; and (5) tubular type. The tight-rope type, consists of a single rope to serve as a footwalk and two side ropes for hand-rails. This type has been mentioned by the English traveler, E. Kingdon-Ward, to illustrate his article[7] on "Bridge Builders of the Jungle." It is a remarkable fact that this same type of bridge was found by an American explorer in the Cameroon—the French mandate in Equatorial West Africa.[8] It was made safer, however, by a woven net of vines extending from the foot-rope to both hand-ropes. This was among the negro race, so far distant from the Aryan people of the high plateau of Central Asia that it is difficult to understand how, even in the long course of history, there could have been any contact with or communication between them.

---

[4] Described in *Merry's Museum,* a serial magazine for young people, more than sixty years ago. Recollection verified by a contemporary reader. Encyclopedia Britannica, Fourteenth Edition, Vol. 18, Article "Primates," pictures the "spider monkey of tropical America, with long arms and long prehensile tails." These would be capable of the performance described.

[5] Appleton's Cyclopedia, Vol. XIII, Article, "Palm."

[6] Webster's International Dictionary.

[7] *Travel,* February, 1931, p. 38.

[8] *National Geographic Magazine,* Vol. 59, February, 1931, p. 231.

In Tibet, rivers are crossed by a single rope which serves, by aid of a trolley block and sling, and a dragline, to transport singly a man, an animal, or a parcel across a stream. (Type (2).)

The toboggan type of bridge (Type (3)) was also described by Mr. Kingdon-Ward.[7] This is a single rope securely anchored to a post or tree higher up than the point of landing on the opposite side of the stream. On this, slides a trolley block from which is hung a sling to support the weight of the traveler. The rope and the block are lubricated by yak butter—a product of Asiatic cattle. Standing in the sling, with his hands grasping only the block, the traveler is started by a push, and the force of gravity rushes him across the torrent with fearsome rapidity. Of course, another rope is set for crossing in the opposite direction.

The roadway type (Type (4)), shown in Fig. 1, needs little description. This example is in the Island of Java—Dutch Colonial territory. Apparently, the span is about 100 ft., and the construction is quite like that which an engineer of to-day would make it with the material at hand.

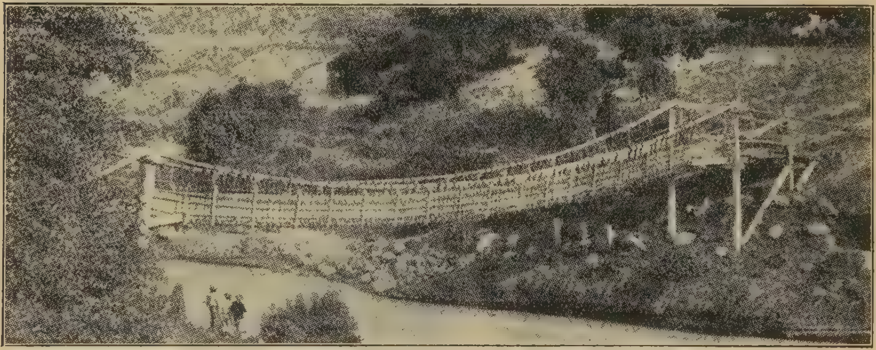

FIG. 1.—HIGHWAY TYPE OF ROPE BRIDGE, JAVA.

The tubular type (Type (5)), shown in Fig. 2, was another found by Mr. Kingdon-Ward among the fierce Abor people on the Assam frontier. It spans the Dihang River, and is nearly 800 ft. long, the center being 50 ft. above the stream. Report was that 200 men built it in about a month, the labor being freely supplied by the villagers who used it.

A variation of the roadway type of bridge is described by Spanish historians as found by the invaders of the Sixteenth Century in the Peruvian Andes.[9] These bridges were composed of four ropes of twisted vines, covered with branches for a floor, and two ropes for hand-rails. To cross comparatively still water several hundred feet wide, the Inca workmen laid two great ropes of twisted grass on the water surface, on which cross-fascines of dry rushes were lashed. Two other ropes were laid on the fascines, which were again covered with smaller fascines, making a floating bridge with a floor, 15 ft. wide, over which armies passed. Such a structure required renewal or repairs every few months. The Incas also used a single rope on which an under-slung hammock was held by clews so as to be drawn back and forth by a dragline. The widespread use of such "prehistoric" bridges in both hemispheres is significant of antiquity.

---

[9] Edinburgh Cyclopedia, 1832, Vol. 4, p. 471.

A French historian maintains that types of bridges found among backward tribes or communities in the hinterland of more advanced civilization are survivals of prehistoric structures with little if any change.[10] In the hills of Savoy in Italy, a primitive bridge was found, the structure of which had changed very little since the time of Julius Cæsar, who described[11] similar structures used by the Gauls, thus:

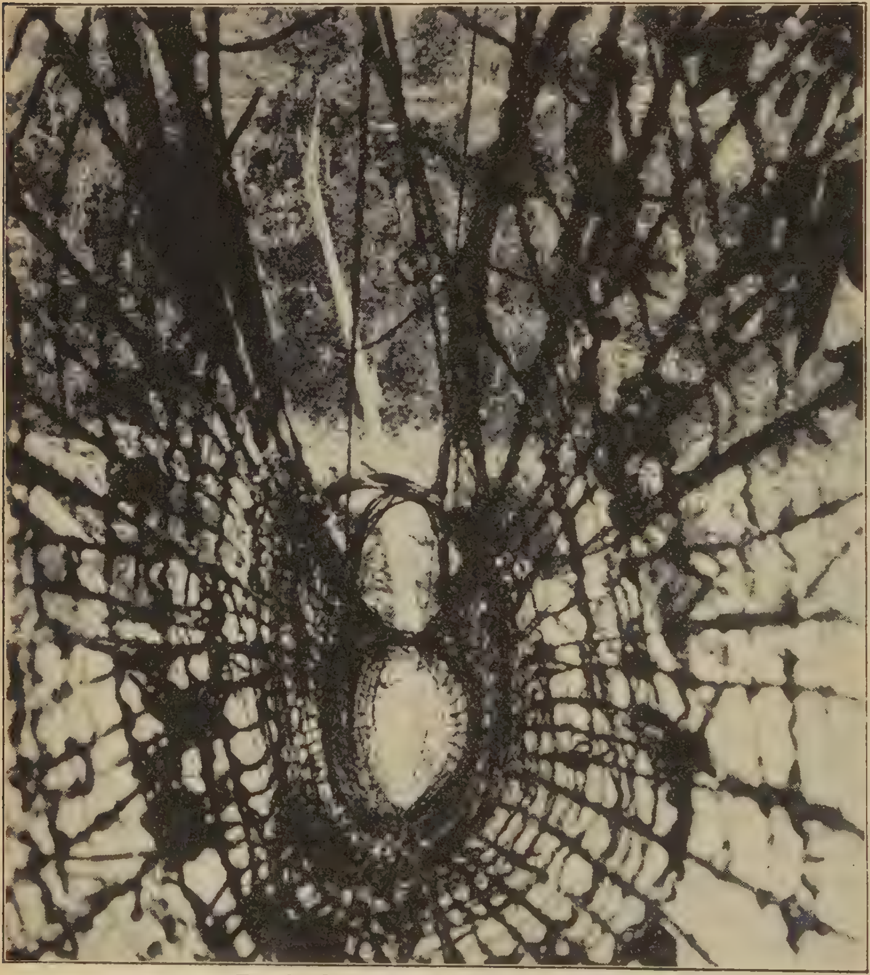

FIG. 2.—TUBULAR CANE BRIDGE, ASSAM.

"It is a timber bridge or empilage, piled together rudely, not constructed by art. It needs no carpentry. * * * On each bank of the stream a rough foundation of water-worn boulders was laid, about fifteen feet square; upon this a criss-cross (crib-work) of the tree trunks was built so that the logs in the direction of travel, in alternate layers, were made to jut out farther and farther over the water, narrowing the gap to be bridged later by a few logs serving as beams."

---

[10] "A Book of Bridges," by Brangwen and Sparrow, Plymouth, England, 1914 (in Dartmouth College Library).

[11] So stated by the author quoted.

Then, a floor of smaller round cuttings laid cross-wise over all made, in modern phrase, a corduroy road. Examples of such bridges in Kashmir, Northern India, and in Bhutan Province, north of Bengal, India, have been published by Charles S. Whitney, M. Am. Soc. C. E. One of these is apparently a development of what may be termed the corbel type into a real cantilever type of bridge. The portal towers, which probably serve partly as anchorages, suggest similar portals of Mediæval Europe. The total span appears to be between 80 and 100 ft.[12]

If prehistoric types survive to-day they would be among people like those of the "unchanging East," little affected by time or political disturbance, where the repairs made necessary by the vicissitudes of climate, decay, floods, and destruction by fire or enemies could be quickly and continuously effected.

The early historical period has little to tell about wooden bridges for many centuries. A writer states[13] that the Greeks, although masters of architecture, built few bridges and points out that "even Athens, with its splendid edifices, had no bridge over the Cephissus which ran athwart the most frequented thoroughfare to the city."

As to the Romans, Messrs. Brangwen and Sparrow state[10] that it has not been possible to learn how the Romans built their timber bridges. Pons Sublicius was a sacred monument, hallowed by traditions; but even this bridge was imperfectly described. According to the aforementioned writers, the most that can be said is that the Pons Sublicius was a tree bridge resting on piles. It dated from the time of Ancus Marcius who reigned from 640–616 B. C. Whether the chief priests did or did not build it, they were faithful in keeping it repaired, since it was in existence as late as the reign of Constantine (306 to 337 A. D.)—at least 900 years.

However, a reliable description is available of the timber bridge built (probably) under direction of the distinguished architect and engineer, Vitruvius, about 2 000 years ago, which permitted the passage of the Roman Army into Germany. This is frequently described as Cæsar's bridge. In his day, Palladio, the Venetian architect (1518-1580), made an exhaustive study of the vestiges of the Roman empire.[14] In his treatise on "Architecture," he gives, in the Latin, Cæsar's description of this bridge and a drawing to show the method of construction. The simplicity of the construction is obvious from Fig. 3. Its ingenuity appears by a brief study of the details, which shows how the parts of the bents lock themselves by action of the notched block in the notches on the cross-girder and inclined struts. Imposed weight simply makes the joints tighter. Thus, these bents could be framed quickly and set in place and could be removed quickly without the use of more elaborate fastenings, which would require time and supplies of hardware. It is on record that the Emperor made Vitruvius Superintendent of *Ballistæ* (Chief of Artillery), and this temporary structure in its design gives evidence of such skill as Vitruvius would doubtless possess. It is scarcely probable that the lumber was as smooth and square as the drawing indicates.[15]

[14] "The Architecture of Palladio," Large folio, with many full-page engravings; translated from the Italian, Lond., 1721.

A little more than a century later (104 A. D.) Trajan's bridge across the Danube River is mentioned in Roman history as one of the most prodigious works ever undertaken by the Romans. Dion Cassius stated that it rested on twenty piers, 150 ft. high and 170 ft. apart. These were united by semicircular timber arches. Perhaps the height was fixed by the high banks of the river. Nicholas Bergier[16] states that the piers of squared-dimension stone were built upon rip-rap dumped upon the unstable bed of the stream and that the legionaries were generally put to work on the roads and bridges to avoid the evils of idleness. Hence, with the customary use of slaves and commandeered labor, the abundance of timber in a wild country, and transportation made easy by the river, work on several piers and timber arches could proceed simultaneously. The carving, showing a span of this bridge, on Trajan's Column in Rome, as illustrated in books, is probably only conventional, since it is not in accord with the description given. Bergier presents long inventories of the roads of the Roman Empire in its greatest extent, from Britain to North Africa, and from Spain to Asia Minor, showing a total of nearly 65 000 miles. As to wooden bridges he states that timber was used in the early stages of road extension, but such bridges were eventually displaced by structures of stone.

LATER EUROPEAN TIMBER BRIDGES

The Sixteenth Century.—The first illustration of a framed truss, in the modern sense, that the writers have yet discovered, appears in Palladio's "Architecture" (Fig. 4). That author states that this truss spanned a mountain torrent in Northern Italy. Apparently, the span is between 50 and 60 ft. The vertical members he terms pillars, or *collonelli.* The peculiar connections for carrying the weight from the cross-girder to the posts are possibly of his "invention," because he describes three "inventions," one of which is similar to Fig. 4, but with curved chords; a second, which has little merit, and a third, the framed arch shown by Fig. 5.

His designs seem to have attracted little attention because there was no further development of timber bridges in Europe until the middle of the Eighteenth Century—a period of rapid progress, when both rulers and people gave more attention to public works of all descriptions and when Civil Engineering began to be recognized as a profession. In this development French engineers took precedence, publishing elaborate treatises on architecture, carpentry, civil constructions, etc. In France, Perronet built his magnificent monumental stone bridges which served as models for English engineers and for those of other lands. He was a Director of "L'Ecole des Ponts et Chaussées," in Paris. English engineers, lacking abundant timber,

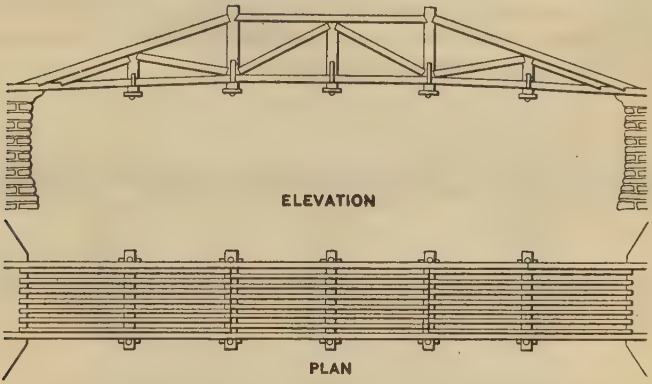

FIG. 4.—A TRUSS DATED ABOUT 1550 A. D.

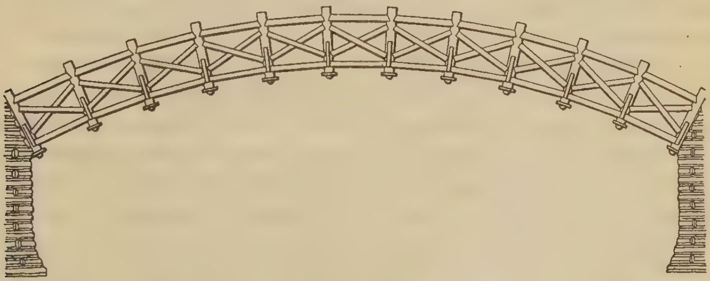

FIG. 5.—PALLADIO'S TIMBER ARCH.

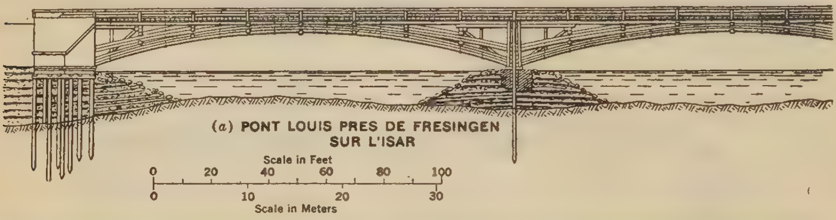
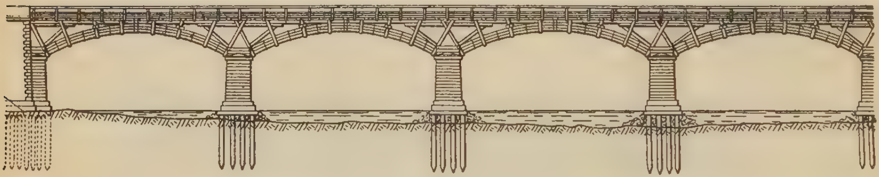
utilized cast iron in some notable bridges standing to this day; but from the first they followed French practice in constructing some famous stone bridges.

The French types of timber bridges had the distinguishing characteristics shown in Fig. 6;[17] namely, level floors, low parapets, and flat arches, usually not framed after Palladio's pattern, but built of plank in layers clamped together. The floors were supported by radial struts attached to the arch and by braces from piers and abutments. The piers, usually of stone, were built at least to the skew-backs of the arches and sometimes to the floor level. The longer span shown (Fig. 6(*a*)) is about 150 ft.; the shorter one (Fig. 6(*b*)), is about 65 ft. In general, the designs produced pleasing architectural effects. Occasionally, piers were in the form of pile bents; and simple pile and beam trestles were resorted to when long spans were not needed.



(*a*) PONT LOUIS PRES DE FRESINGEN SUR L'ISAR



(*b*) PONT DE CHOISY SUR LA SEINE

FIG. 6.—EUROPEAN TIMBER BRIDGES, EIGHTEENTH CENTURY.

Covered or roofed-in bridges were distinctly not a feature in European practice. Two notable Swiss bridges, built by the Grubenmann Brothers, were exceptional. The picture of the Schaffhausen Bridge has appeared in so many books and atlases as to be familiar to engineers generally. Fig. 7[18] shows the greater part of one span, with the details fairly distinct. It has been overpraised. It was a ponderous combination of long and short braces extending from as many points as possible to both abutments—a maze of timbers, scarfed, bolted, strapped, and clamped together to form nondescript trusses. The roof was top-heavy, with a needless amount of timber. It had two spans of 171 and 193 ft., propped by abutment braces. It was finished in 1758 and destroyed by the French in 1799. The one at Wittingen, Germany,[19] had a single span of 390 ft., making a stretched-out and awkward truss lacking the appearance of adequate strength. Neither bridge was worthy of consideration from an engineering standpoint. The assertion of an English writer that these bridges suggested the idea of the American covered bridge, with its roadway between trusses, is not justified by the facts. The early American types developed in the last two decades of the Eighteenth Century, and later, have little resemblance to those structures.

AMERICAN TIMBER BRIDGES

Development of Types.—The first settlers along the Eastern Coast of America found themselves in comparatively flat country, intersected by broad estuaries and tidal marshes. These conditions sometimes required bridges of considerable length and low elevation which were readily and inexpensively constructed by adopting pile bents and short spans. As loads were light, beams of moderate size were sufficient.

An authoritative history of this development was begun by the late Theodore Cooper, M. Am. Soc. C. E., in a paper presented to the Society more than forty years ago.[20] His short section on wooden bridges begins with the year 1660, thirty years after the settlement of Boston, Mass. He mentions "The Great Bridge" built in 1660, across the Charles River, which was 270 ft. long, on 13 piers. Twenty-five years later, another bridge was built over the same river, 1 503 ft. long, on 75 piers; the West Boston Bridge over the Charles River, 3 500 ft. long, on 180 pile bents, was finished in 1793; and in the same decade a pile bridge, a mile long, in 25-ft. spans, was erected over Cayuga Lake in New York State. In 1792, a bridge was built by Col. William P. Riddle over the Merrimac River, at Amoskeag Falls, now Manchester, N. H. This bridge was about 556 ft. long, supported by five cribwork piers filled with stone, and connected by beams not longer than 40 ft., which were then readily procurable from the great pine forests. Even before that, the Northwestern frontier had been pushed into Vermont, and a bridge was needed over the Connecticut River.

Colonel Enoch Hale's Bridge

In 1785, Enoch Hale built a notable bridge over the Connecticut River, at Bellows Falls, Vt. He was born in 1735 at Rowley, Mass., and moved to Rindge, N. H., in 1760, before it was incorporated as a town. He soon became prominent in the community, holding finally the office of High Sheriff of Cheshire County. In 1783, he obtained a grant from the Legislature to build a toll bridge over the Connecticut River between Walpole, N. H., and Rockingham, Vt. In 1784, he moved his family to Walpole and completed the bridge in 1785, two years after the close of the Revolutionary War. The bridge crossed the gorge at Bellows Falls, the narrowest point of the river where there is a rock reef dividing the water into two channels. This was the first bridge over the river at any point and while it was being built, the residents looked upon it as a foolhardy experiment. It is reported by contemporary newspapers to have been 365 ft. long, in two spans, supported at the center on the natural rock pier.

Fig. 8 is a sketch from an oil painting of the locality, showing the original structure, or a successor to it. The date of the painting is uncertain. Undoubtedly, the type shown represents that built by Enoch Hale. It consisted of four lines of braced stringers said to have had spans of 98 ft. each at the foot of the braces. The floor was at least 50 ft. above the water. It was the first bridge built in America with spans greater than could be negotiated with single stringer sticks; and, therefore, richly deserved the fame accorded to it.

---

[20] "American Railroad Bridges," *Transactions*, Am. Soc. C. E., Vol. XXI (July, 1889), p. 1.

The building of this first bridge over the river was noted far and wide. It was considered a remarkable feat of construction. It was reported in many newspapers[21] and was hailed as opening the Vermont region to the trade of Boston and the coast towns of New England generally. It was visited by prominent men. The Rev. Timothy Dwight, President of Yale College, speaks admiringly of it in several of the narratives of his trips up the river. Without doubt the successful building and use of this bridge inspired the building of others in various sections during the next ten or fifteen years.

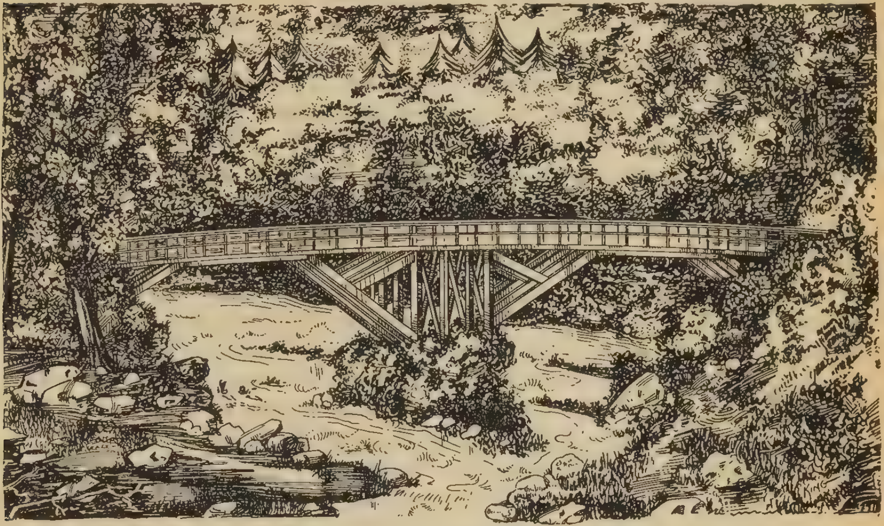

FIG. 8.—ENOCH HALE'S BRIDGE, BELLOWS FALLS, VT.

TIMOTHY PALMER AND HIS BRIDGES

One of the most ingenious and famous of the bridge builders of this period was Timothy Palmer, of Newburyport, Mass., greatly distinguished as a civil engineer (1751-1821). He may well be called the Nestor of American bridge builders. The principal bridges on the Kennebec, Piscataqua, Merrimac, and Connecticut Rivers were built on his models. Mr. Cooper gives a view of the Essex-Merrimac Bridge, built by Mr. Palmer, three miles above

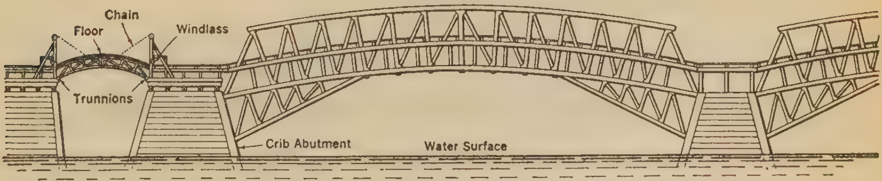

FIG. 9.—ARCH BRIDGE BUILT AT HAVERHILL, MASS., IN 1794.

---

[21] *Massachusetts Spy*, February 10, 1785.

Newburyport in 1792.[22] It consisted of two arched spans, one on each side of Deer Island. The Piscataqua Bridge, built in 1794, had pile trestle approaches to an arch which was esteemed a wonder at the time, and the Haverhill Bridge, built the same year, has three arches so similar that Fig. 9[23] will serve to illustrate all three bridges. Mr. Cooper, quoting from a contemporary, describes[24] the Piscataqua Bridge ("The Great Arch") as a masterly piece of architecture. Its length was 244 ft., the rise was 27 ft. 4 in., and the depth of framework of the arch, 18 ft. 3 in. There were three concentric ribs, the middle one carrying the floor of the bridge. The ribs were made from crooked timbers, so that the fibers were nearly in the direction of the curves, and they were connected by pieces of hard and incompressible wood, with wedges driven between. The ribs were mortised to receive these connecting pieces and wedges, thus keeping an equal and parallel distance between them. Each rib was formed of two pieces, about 15 ft. long, laid side by side in such a manner as to break joints. Their ends all abutted with square joint against each other, and were neither scarfed nor mortised, the two pieces of timber being held together by transverse keys and joints. All the timbers were admirably jointed and freely exposed to the action of the air. Any piece might be removed for replacement without injury to the remainder of the structure. Another account states that, of the three ribs or tiers of girders forming the framed arch, the second or middle one supported the roadway, which was 33 ft. wide, and the third served for a railing.

An inspection of Fig. 9 shows a general conformity to the description of "The Great Arch." The short span of 30 ft. at the left is a draw-bridge over the channel. A feature of these bridges that should be noted, is the long braces at the ends, reaching from points half-way down on the abutments to points three-panel lengths forward on the truss.

Ten years later, in his "Permanent Bridge" (Fig. 10), built over the Schuylkill River (1804-1806), at Philadelphia, Pa., Mr. Palmer changed the type radically. The three spans, two of 150 ft. and one of 195 ft., are continuous over the piers, and there is no bracing beneath the arches. The floor is supported by a heavy continuous string-piece notched into the uprights of

[22] *Transactions*, Am. Soc. C. E., Vol. XXI (July, 1889), p. 4, Pl. I.

[23] This was copied from a pen-and-ink sketch made in 1797, now bound with some manuscripts in Boston (Mass.), Public Library.

[24] *Transactions*, Am. Soc. C. E., Vol. XXI (July, 1889), p. 3.

the continuous arched truss. The large timber available allowed deep notching and the tension members required projecting ends sufficient to resist shearing. Treenails were used instead of bolts and the timber was the best selected white pine. Meantime, in 1796, Mr. Palmer built a bridge over the Potomac River, at Georgetown, D. C., and secured a patent "for his improvement and construction of bridges." He insisted upon the necessity of protecting bridges from the weather, modestly stating that such precaution might extend the life of the bridge from ten to twelve years to as many as forty years. Whether his were the first of the covered bridges is not known.

His bridge over the Delaware River, at Easton, Pa. (Fig. 11), requires special notice as indicating Mr. Palmer's under-estimate of the durability of his work. The obvious changes from the type of the Schuylkill Bridge are the level floor, the straight upper chord, and the flatter arch. The details to be noted are the slotted bolts, the keys, and wedges. Treenails (commonly pronounced "trunnels") are in evidence here, also. A recent report[35] states that it was opened as a toll bridge in 1806 and completed a year later, at a total cost of $61 000. It was always covered from the weather, and was removed in 1895, not because of decay, but because it became inadequate for the traffic when horse-cars were replaced by trolley cars. In other words, it was strong enough, after ninety years, for the loads it was designed to sustain.

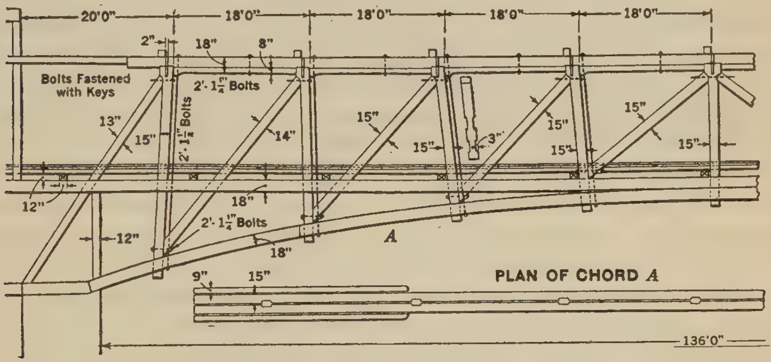

Fig. 11.—Palmer's Bridge Over the Delaware River, at Easton, Pa. (1807).

In Fig. 11, attention should be directed to the style of connections. The bolts at the top of the posts are slotted and held in place by wedge-shaped keys or "fids." These bolts can be driven like drift-bolts in holes of the same size as the bolts, and can be "set up" or drawn in, as the timber shrinks, by re-driving the "fids," or inserting a washer if necessary. Hence, they serve both as treenails and clamps, while a drift-bolt alone serves only as a treenail, and a screw-bolt only as a clamp.

The Second Connecticut River Bridge.—Little more than a decade after Colonel Hale's bridge, a second bridge was built across the Connecticut River which was to be a link on the projected highway connecting Boston with

---

[35] Letter from State Highway Dept., Trenton, N. J., March, 1931. Information from Department records, through Roy Mullins, Highway Engr.

Northern Vermont. It joined the Towns of Hanover, N. H., and Norwich, Vt. Dartmouth College was influential in promoting the project. Professor J. K. Lord is authority for the information that[26] in 1796 one, Rufus Graves, built a bridge consisting of a single arch of 236-ft. span (similar to Fig. 9) at this point. The over-all length of the bridge was 344 ft., its width, 36 ft., and its stone abutments, 40 ft. square. It was arched to such a degree that the roadway at the center of the bridge was about 20 ft. higher than at the ends, presenting thus a sharp ascent on entering and a corresponding downward pitch on leaving. It was built of the largest selected pines, 60 ft. long, many of them hewed 18 in. square. The bridge fell by its own weight in 1804. On the testimony given by President Dwight, of Yale College, and others, it seems to be quite probable that Graves' bridge was patterned after the Piscataqua arch, but the builder lacked Palmer's experience and skill.

Lewis Wernwag and His Bridges

Lewis Wernwag was born in Germany in 1770. He died at Harpers Ferry, Va., in 1843. A letter written by his son, John,[27] to the late Samuel L. Smedley, M. Am. Soc. C. E., includes a list of twenty-nine bridges that Wernwag built during the twenty-seven years of his active career in Pennsylvania, Maryland, Virginia, Kentucky, Ohio, and Delaware. He was an original genius. His most noteworthy accomplishment was his "Colossus," built in 1812 over the Schuylkill River at the then, "Upper Ferry," later, Fairmount, Pa. This bridge, with a clear span of 340 ft. was composed of five parallel arched trusses, each with a rise of 20 ft. The roadway, however, had less than one-half that rise. Apparently, he originated the type. This bold design, scientific and architecturally beautiful, probably was never surpassed in America. One Swiss bridge has been mentioned, with a longer span by 50 ft., but compared to this, it was a monstrosity without merit. The cross-section shows the two roadways and two footwalks.

Wernwag did not take out a patent until 1829 and his drawing[27] shows iron rods in every panel, which were intended to act partly as counters and also to adjust the joints if they worked loose. The comparatively light traffic loads of those days would cause but little reaction against the dead weight of such a heavy bridge. The arch was built up in seven layers, and had a total depth of 3 ft. 6 in., and a width of 13 in. Fig. 12 is from the patent drawing and Fig. 13[28] is a full span view of the bridge.

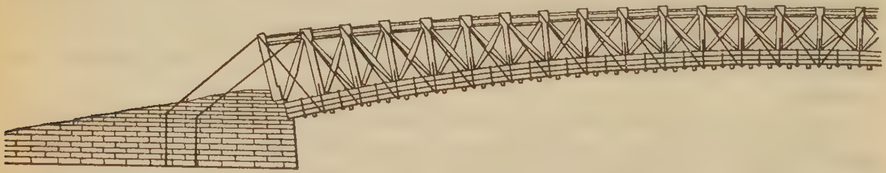

Fig. 12.—Longitudinal Section, The Upper Schuylkill River Bridge, Philadelphia, Pa.; "The Colossus."

---

[26] "History of Dartmouth College," by J. K. Lord, p. 657.

[27] *Engineering News*, Vol. 14, (1885), p. 99.

[28] Copied from a large atlas of "Notable Bridges," pub. in London, England, in 1825.

In describing the bridge, Wernwag himself states that dry-rot was prevented by sawing the timbers through the heart to discover defects. The timbers were kept apart by iron links and screw-bolts and were neither mortised nor tenoned, except at the king-post and truss ties. No timbers were allowed to come in contact, and provision was made to tighten necessary bolts as the timber tended to shrink, and any piece could be replaced without injuring the superstructure. The trusses were stayed at the ends by two long iron rods, one attached at the top of the end-post, the other at the top of the second post. Both extended downward at an angle of about 45° and were anchored at the back of a long and massive abutment built with squared-dimension stone laid in parallel courses.

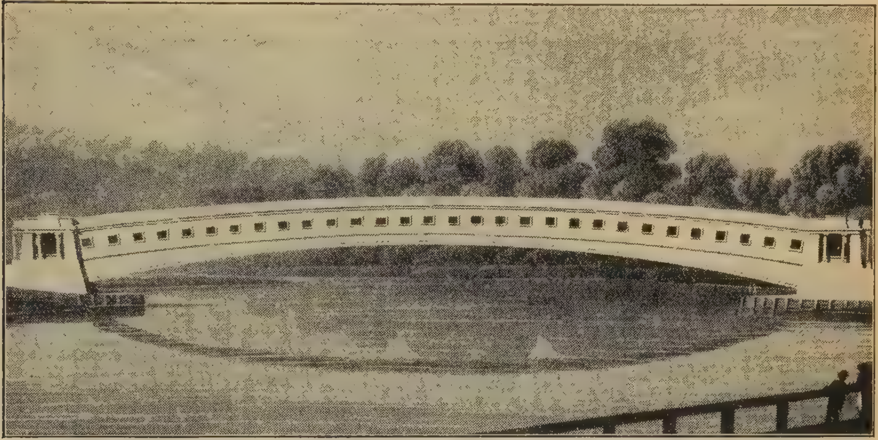

FIG. 13.—THE "COLOSSUS" OVER THE SCHUYLKILL RIVER, AT PHILADELPHIA, PA. (1812).

In 1813-14, Wernwag built a bridge of quite a different type over the Delaware River, at New Hope, Pa. This had trusses with parallel chords, vertical timber posts, and iron rods for diagonals, anticipating what was known later as the Pratt type. The principal feature was the arches which rested on top of the abutments. In other respects, it was based on the same principle as "The Colossus" (Fig. 13) with the addition of the floor chord connected with the casting in which the arch rested, which prevented it from shoving against the pier or abutment.

In 1810 Wernwag constructed a bridge over Frankfort Creek between New York, N. Y., and Philadelphia, which was named "Economy." It was a cantilever[29] type designed so that the center panel could be tipped up in order to pass masted vessels through.

THE BURR TRUSS

Many famous bridges of various designs were built by Theodore Burr, of Massachusetts, during the first two decades of the Nineteenth Century. Fig. 14 illustrates a truss bridge built for railroad service over the White

---

[29] *Engineering News*, Vol. 14, 1885, p. 99.

River, at White River Junction, Vt. The photograph was taken when the bridge was being removed in 1890, to be replaced by an iron bridge. It was a splendid example of the Burr type, built in 1848 of old growth white pine when large sticks were available; the end-posts were 18 in. square. The hanger rods were inserted after the bridge was built, to assist in carrying the floor load to the arches as engine loads became heavier. The masonry of this bridge was all quarry-faced granite ashlar laid with very close joints without mortar. At the right end is shown a corner of the north abutment. The abutment wings are circular arcs tangent at the face of the abutment, to a line parallel to the track, presenting the resistance of an arch to the pressure of the earth-fill. The bridge was as strong and serviceable after fifty-four years as when it was built. The entire combination—substructure and superstructure—was capable of much longer service than it rendered. Mr. Burr's first bridge was erected in 1804 over the Hudson River between Waterford and Lansingburgh, N. Y. (Fig. 15). This was followed by a bridge over the Delaware River, at Trenton, N. J., completed in 1806, which carried two roadways and two sidewalks by five arches;[30] the Mohawk River Bridge (1808), at Schenectady, N. Y., which Mr. Cooper

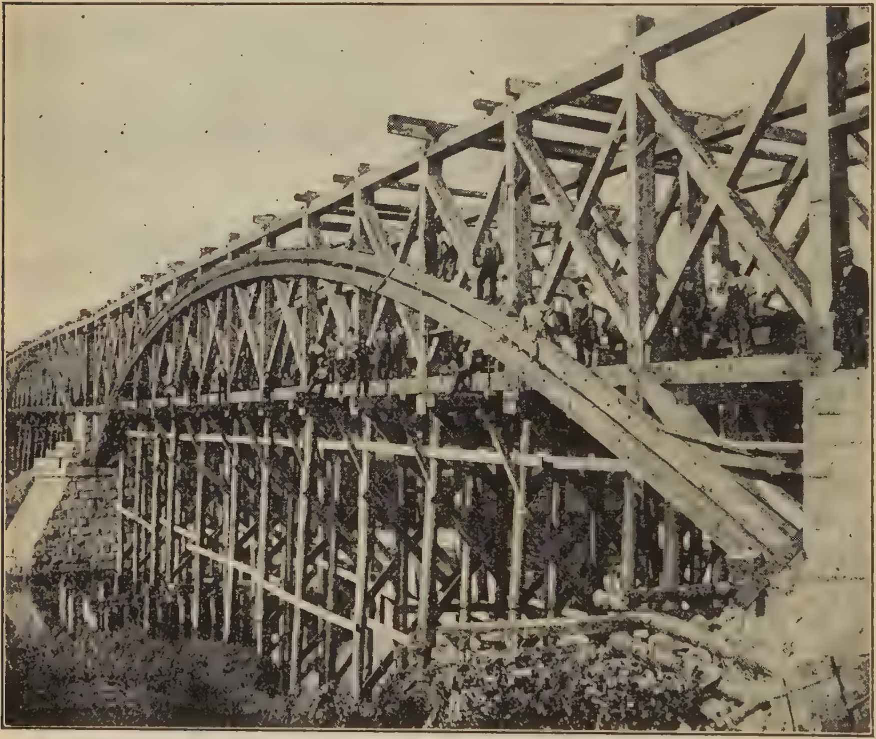

FIG. 14.—BURR BRIDGE OVER THE WHITE RIVER, WHITE RIVER JUNCTION, VT. (1848).

---

[30] *Transactions*, Am. Soc. C. E., Vol. XXI (July, 1889), Pl. VII.

described[31] as a wooden suspension bridge; and the long bridge over the Susquehanna River, at Harrisburg, Pa., a wooden arch bridge of twelve spans completed in 1816, on a radically different plan from that of the Trenton Bridge.

These four bridge types seem to have been experimental, in a sense, with Mr. Burr. His patent, dated 1817, which included a drawing of the Waterford Bridge type shown in Fig. 15, ultimately claimed nothing but the arch combined with the truss, the arches springing from the face of the abutment below the bridge seat. Although this bridge was built a year or two earlier, it looks as if it might be a derivation and improvement of Palmer's Easton Bridge (Fig. 11). The parallel chords of the trusses made ideal supports for the roof and floor, its posts and other members were firmly connected with the arches at each panel point, thereby acting perfectly as stiffeners for the arches. The bridge presents a combination of features the theoretical value of which was little realized by Mr. Burr. The other types, built with splendid workmanship, did commendable service, except the Mohawk River anomaly which had to be held up by a trestle after twenty years of use. The Waterford type, under the name of the Burr truss, was used all over the United States as long as purely wooden trusses were built. The type is well adapted for deck bridges, but few prominent instances of such use have come to the notice of the writers. In this type, Mr. Burr really inaugurated the combined arch and truss which has developed in Twentieth Century steel bridge practice, through the spandril-braced arch into the great braced arches at Hell Gate and Kill van Kull, in New York Harbor, and at Sydney, New South Wales, Australia. What are they but two-ribbed arches with stiffening trusses built between?

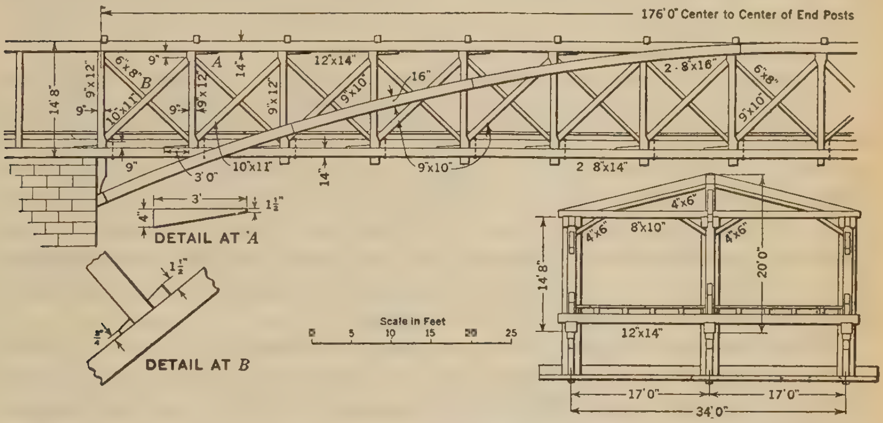

FIG. 15.—HIGHWAY BRIDGE OVER THE HUDSON RIVER BETWEEN WATERFORD AND LANSINGBURGH, N. Y., BUILT BY THEODORE BURR.

The Waterford Bridge, previously mentioned, consisted of four spans of from 154 to 180 ft. clear. It did duty for 105 years without material strengthening until 1909, when it was destroyed by fire. The large timber available and the relatively light loads on bridges in this period of dirt roads rendered these bridges appropriate for the time, although they were frequently designed quite unscientifically. The posts were hewn, not only to make seats for the main diagonals, and for bearings on the arches, but were notched at the lower chord intersections. They acted in tension and had to be framed accordingly. The arches were 4 to 8 in. thick and were attached to each side of each truss. In case of unusually long spans concentric arches were used.[31a] Hundreds of highway bridges framed more or less (generally less), on the Burr principle, were built in various parts of the Eastern and Middle States and in New England. Many of these are still standing. Their longevity is remarkable, if properly protected by roof and side covering. The siding should leave a vertical space at the top about equal to the overhang of the roof; it should be vertical and nailed at the bottom to a girth furred out from the chord to leave a space so that dirt will not collect on the chord. Spans longer than 50 ft. should be reinforced by arches.

---

[31] *Transactions,* Am. Soc. C. E., Vol. XXI (July, 1889), Pl. VIII.

The timber in these early bridges was generally white pine which was a factor in their longevity. One at Springfield, Mass., was 104 years old when removed. Two over the Ammonoosuc River, one at Woodsville and the other at Bath, N. H., built in 1828, are still standing (1932). One at Greenfield, Mass., built in 1840, carrying all the traffic from the south, bound for the Mohawk Trail, survived in good condition until June, 1932, giving way then to a new bridge on a revised location. Many of the picturesque old covered bridges still dotting the New England landscape are of the Burr type, most of the shorter ones being without arches.

The longest single span of framed wooden bridge (262 ft.), since Wernwag's "Colossus," of which the writers have knowledge, crossed the Delaware River at Narrowsburg, N. Y. (1859). A system of struts between the posts below the upper chord to resist the horizontal thrust of the main braces, was an unusual feature in a Burr truss.[32] Attention is called to the unusual application of four separate and parallel arches in each of the trusses.

The Town Lattice Truss

Ithiel Town, of New Haven, Conn. (1784-1844), was granted a patent on a plank-lattice design for bridge trusses in January, 1820. It represents a lattice web, more suitable for a fence than for a bridge truss. Town secured a patent in 1835 for double webs and secondary chords.

A double-web truss of this type, with secondary chords, is shown in the paper by Mr. Cooper,[33] but it lacks much in the line of bracing and end support for the short lattice. It shows an unusual and unnecessary prolongation of truss over the abutment. It is true that this type requires a wider seat on the masonry than the Howe and Pratt types, in which the entire reaction is concentrated at a single panel point; but the additional masonry required for the lattice type is negligible if the parapet and wings are adjusted properly. Mr. Cooper, and other writers, state that these lattice-truss bridges are unsatisfactory on account of warping and getting out of line. This cannot be wondered at if lower lateral and effective transverse bracing are omitted, as is the case with the drawings usually shown. The scant justice done this type of truss by writers heretofore, is the warrant for recording its merits and according it considerable space in this paper.

[31a] See Fig. 14.

[32] *Engineering News*, Vol. 42, 1899, p. 122.

[33] *Transactions*, Am. Soc. C. E., Vol. XXI (July, 1889), Pl. X.

Railroad freight traffic in the United States has become so enormously heavy that its economic handling requires equipment so ponderous that wooden truss bridges have become obsolete, even on branch lines, because rural industries must transport their supplies and products in the same equipment that is used on the main lines. On account of the common neglect of rural highway bridges it is generally advisable to recommend concrete structures where facilities for assembling materials therefor are reasonable; but where suitable lumber for lattice bridges is abundant and where fabricated steel is costly, as was the case in New England during the Nineteenth Century, and is now the case in Southern Alaska, Northern Russia, and Siberia, and perhaps in some parts of South America, lattice-truss bridges are economical and can be made perfectly good up to spans of 200 ft. for railroad trains not exceeding Cooper's E-40 loading. If properly covered and maintained, such bridges will give from 50 to 100 years' service.

As stated by Mr. Cooper, this truss has been built in many parts of the United States for railroads where suitable timber was plentiful and cheap. It has also been extensively used for highways before and since the advent of railroads in the Valleys of the Connecticut and Merrimac Rivers, in New Hampshire and Vermont. This and modifications of the Burr truss were the favorite types in building the picturesque old covered highway bridges, so many of which dotted the New England landscape and many of which still remain.

In 1900, at least 100 bridges of this type were extant on the Boston and Maine Railroad System.[34] They had been built largely on the "try-and-fail" method by local carpenters who adopted bridge building as their life-work. The best of these bridges, although built without any knowledge of unit strains, were quite satisfactory under the trains then using them. Common defects were lack of effective horizontal and transverse bracing, inadequate splicing of tension chord planks, and unsafe floors under derailed cars. Notwithstanding these defects, due to lack of scientific design, it is remarkable how well the "try-and-fail" method served, in the hands of the naturally competent mechanics of the Nineteenth Century, to produce bridges adapted to the loads and speeds using them. The excellent workmanship of Timothy Palmer's forces in building the "Permanent" bridge (Fig. 10) is typical of the work done by the early builders of these bridges.

Later practice on the Boston and Maine Railroad developed trusses designed more scientifically to overcome the lack of lateral and transverse bracing in the older bridges, as well as to provide for increasing weight of rolling stock. Fig. 16 shows details that have served to keep these structures straight and upright for thirty years and more, although subjected to loads far heavier than those for which they were designed.

Fig. 16.—Town Lattice Truss.

The distinctive characteristics of the Town lattice are its use of simple sizes of lumber, the small amount of framing required, and the need of nothing but bolts and a few round rods for metal work. In such regions as those mentioned, far from centers of skilled labor and steel fabrication shops, the simple character of materials and labor required by this type is important. The trusses are generally built of uniform sections throughout. While this is a feature that is often criticized as wasteful of material, such waste is much more than balanced by the resulting simplicity of framing and erection.

The Town lattice principle is similar to that of the English iron riveted lattice. Both will stand more abuse from service than any other type of truss. Both will give indications of distress long before collapse, and those that were properly built are found doing duty far longer than many other types. The most successful early builders of wooden bridges placed much emphasis upon the necessity of protection from the weather by roof and side covering. All later experience has proved that bridges not so protected deteriorate rapidly.

Until about 1890, lattice bridges could be built with spruce lumber (then costing about $18 per 1 000 ft. B. M.) for one-half the cost of iron bridges. Twenty years after that date (1910), steel bridges could be built as cheaply as those of wood; and now (1931) steel construction is much the cheaper. Computation for designs of this type is simple, following the methods commonly used for computing plate girders.

The accepted construction and a few important details are shown in Fig. 16. The timber ordinarily used in New England has been spruce, with the exception that for the longer spans Southern long-leaf pine was used for lower chords. The pins were of oak, 2 in. in diameter; and it was considered good practice to soak them in lubricating oil. Steel pipes are now being used in British Columbia for these connections. The stringers are gained over the lower lateral braces and rods. The upper laterals are 6 by 6-in. braces and $1\frac{1}{8}$-in. rods in nearly square Howe truss panels, with independent cross-beams and a transverse tenoned brace near each panel point. Turnbuckles in all lateral rods assist in keeping the bridge in order. The floor-beams are spaced to cut the ends of the tension diagonals less than those in compression. To secure sufficient strength in the lower chords of bridges without arches it has been found advisable in some cases to use iron couplings, as shown in Fig. 16. These are computed to add 16 900 lb. to the section if built as shown.

Noteworthy Bridge Builders.—Mr. Town was a promoter and salesman rather than a builder like his predecessors Palmer, Wernwag, Burr, etc. He sold rights to build his design, published advertising pamphlets, made a trip to Europe, and exhibited business ability of high order.

Sanford Granger (1796-1882), of Chesterfield, N. H., established his home at Bellows Falls, Vt., and became a contractor for bridge and building work. There is a tradition that he patented the lattice type of bridges, but it is more probable that he acquired territorial rights from Ithiel Town to build them. He organized a crew for building this type of bridge and constructed many in Southwestern New Hampshire and Eastern Vermont.

Nicholas Powers (1817-1897), of Clarendon, Vt., during the middle of the Nineteenth Century built many bridges over a wide section of country from Maine to Maryland. His was the famous Blenheim, over Schoharie Creek, in New York State, described subsequently. As Superintendent of Construction he built the great railroad bridge at Havre de Grace, Md., over the Susquehanna River; and as Designer and Builder, many of the covered bridges in Vermont and vicinity were due to him.

Dutton Woods (1809-1884), born in Henniker, N. H., adopted bridge building as a life work in 1837 when railroad construction began to be active. He erected many bridges of various types as desired for several railroad companies from New Haven, Conn., to Concord, N. H., and farther north, as well as many highway bridges for various towns and cities. His favorite type in later years was the Town lattice. He used plank arches where needed. He held the position of Superintendent of Bridges on the Concord Railroad until his death.

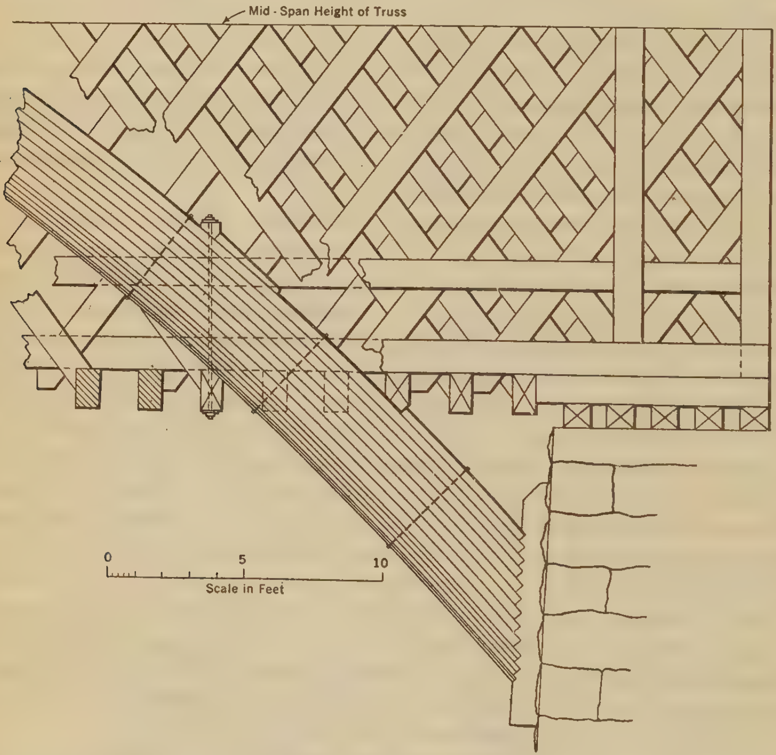

FIG. 17.—TOWN LATTICE TRUSS, WITH BUILT-IN ARCH.

The Childs Brothers, also of Henniker, N. H.—Horace, Enoch L., and Warren S.—built many bridges throughout New England both for railroads and highways, often in conjunction with Dutton Woods. Horace was the carpenter, Warren the stone mason, and Enoch, the Yale graduate and architect-engineer.

David Haselton, born in Dorchester, N. H., in 1832, deserves mention as a builder of lattice bridges after 1860. He was Superintendent of Bridges and Buildings on the Boston and Lowell Railroad until 1890, when it was leased to the Boston and Maine.

Supplemental Arches.—Spans of more than 80 ft., depending on the load, should be built as combined truss and arch. Ordinarily, a single arch on the center line of the truss is sufficient, but, if desired, an arch may be built on each side of the truss, Burr fashion. These arches spring from skew-back blocks scribed to fit the masonry below the bridge seat. The arch planks are firmly held together by radial bolts, and the load is applied by vertical suspension rods carrying needle-beams below the lower chords, or by passing through the floor-beams if they are underhung. These suspenders (or posts when over that part of the arch near the end which is below the lower chord) should be not more than 10 ft. apart along the arch to prevent it from buckling on account of its laminated structure. Fig. 17 shows this construction.

Combinations of arch and truss have been disapproved by schoolmen because of the impossibility of determining the theoretical distribution of stress between the truss and the arch; but if there is strength enough in both, and they are properly yoked together, the safe elasticity of the wood and the connections will take care of the distribution. The Town lattice is the best of the various types of wooden trusses to serve as an arch stiffener because its web members serve either as counters or main braces. The value of arches framed with trusses, if heeled against the masonry, has been amply demonstrated by other types of trusses, some of which have stood for a century. If these arches are sprung from the lower chord the purpose of using them is defeated.

Highway Bridges.—Hundreds of highway bridges have been built with lattice trusses, mostly with single lattice; that is, with one web system per truss. Fig. 18 shows such a bridge of two spans built in 1840 and removed in 1930 to be replaced by a two-span concrete arch structure. This bridge replaced the successor of the famous Enoch Hale Bridge (Fig. 8), and was on the identical site, about 15 ft. higher than the old one. It failed from neglect of a decayed wall-block which led to irreparable injury to one truss. It was 262 ft. long over all. Tolls were eliminated in 1904.

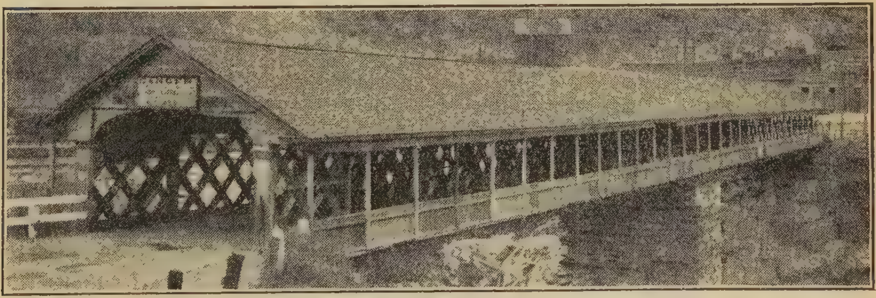

FIG. 18.—TUCKER BRIDGE, BELLOWS FALLS, VT. (1840).

The Timber Lattice.—The type of truss shown by Fig. 19 has been used extensively for highways in the Connecticut River Valley and especially in Vermont, and, in a few instances, for railroad bridges. It is not known who first adopted it,[34a] but its merits have been abundantly proved. The arches shown below the chord were added in 1927 to relieve a decayed lower chord.

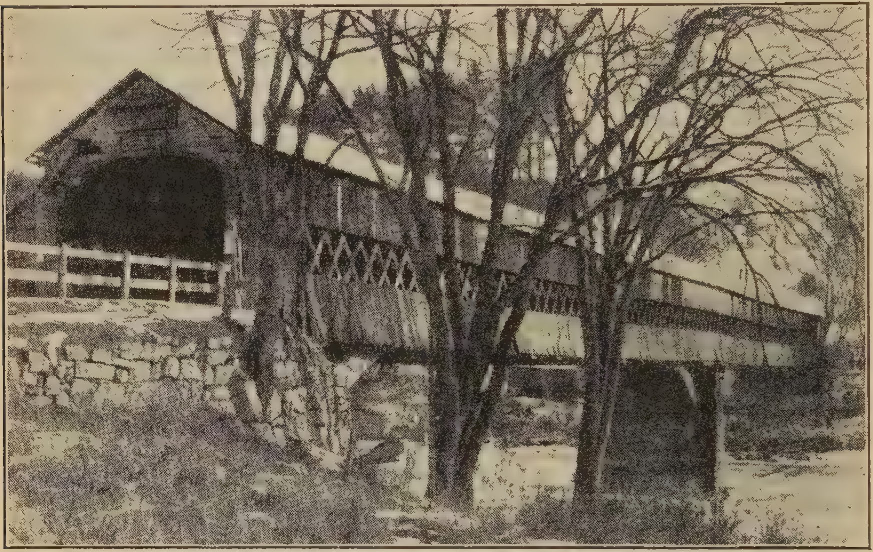

Fig. 19.—The Ledyard Bridge, Hanover, N. H. (1859).

Several highway bridges of this type built 60 or 70 years ago are now standing, some with spans of 160 to 180 ft., over the Connecticut River. The most common reason for unsatisfactory conditions in this type is decay of some part not effectively protected or not renewed in time. In common with plank lattice of their time, built without knowledge of unit strains, they are frequently weak in the tension chord and deplorably deficient in floor-beam strength. (Blenheim Bridge, a different type, shown in Fig. 20, is mentioned subsequently.)

Unlike railroad through bridges, the trusses of highway bridges are not of great height so that they seldom suffer from lack of transverse or lateral bracing. Their plank floors, unlike the open floors of railroad bridges, make the best kind of lateral bracing. The usual construction is a web composed of intersecting joists, 6 by 8 in., or larger, set with broad sides parallel to the plane of the truss, in panels of about 4 ft. which, with trusses of approximately 16 ft., out to out of chords and a run of three panels, make seven crossings of each web member in its length.

At these intersections each member is notched 1¼ in., making the web 9½ in. thick. Where the members pass through the chords, both web members and chord-sticks are notched 1 in. each, leaving 7½ in. of net timber for the web and 5½ in. clear between the sections of the chord. For spans of less than 75 ft., secondary chords are not needed. The ends of the diagonals should be cut not less than 9 in. vertically from the chord, in order to allow a safe length to resist the longitudinal shear.

[34a] Ithiel Town obtained a patent on it in 1839, p. 332.

Pony Trusses.—For spans ranging from 30 to 50 ft., pony trusses have been used extensively. Modified Howe trusses with inclined end posts, Town lattice, and mongrel types are common. The trusses of this class must be stayed by sway-braces. It is not good practice to set these braces on an extended floor-beam because each passage of a load would throw the top of the truss back and forth on account of the deflection of the floor-beam. The needle-beams carrying these braces should be blocked down so that the stringers shall not rest on them.

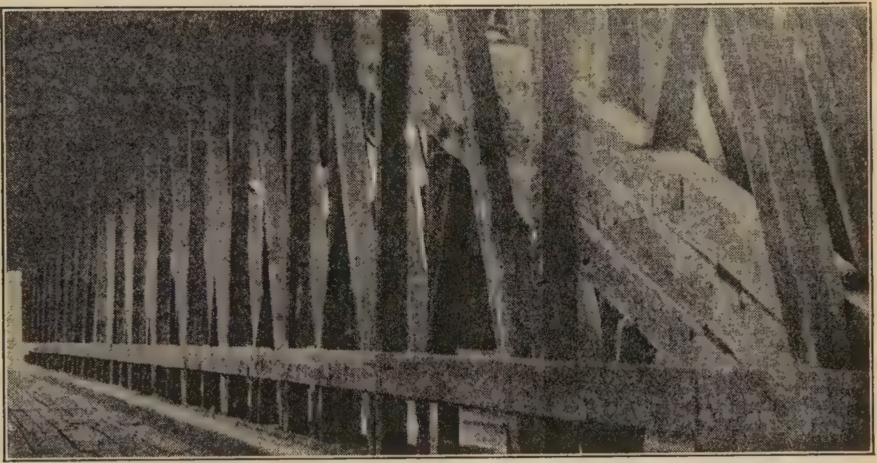

FIG. 20.—BLENHEIM BRIDGE, SCHOHARIE COUNTY, NEW YORK (1855).

Stringer Bridges.—A history of wooden bridges would not be complete without mention of the humble stringer bridge which was, of course, the earliest recourse of man for crossing deep streams, as stated under "The Ancient Background." In American Colonial days just such structures with log cribs or rough stone abutments and round logs hewn on top to receive a plank floor were used for openings up to 40 ft. For wider streams pile or frame trestle bents were used in quiet waters and log cribs filled with stone where heavy freshets occurred. In the days of large timber and of dirt roads this type sufficed for highways, but with railroads, spans of plain stringer bridges were limited to about 15 ft. Fig. 21 shows a type of single-track, pile-stringer bridge of the last decade of the Nineteenth Century.

For spans from 15 ft. to 30 ft., compound keyed stringers have been found useful. Fig. 22 shows the details. The keys shown are cast iron and are proportioned for the longitudinal shear and, hence, the total depth of the compound stick can be used in computing its moment of resistance. They are placed as nearly as may be in accordance with the intensity of the shear. The thin fin at the middle of the key is cut into the wood to hold the key from working out of place.

Fig. 22 shows the junction of a compound and single stringer on a trestle bent. The pile-cap is called a "girder cap with rider"; it is used only on first-class pile work. For lower grade pile work and for framed bents, solid caps, either tenoned or drift-bolted to the pile or post, are used.

Although it can be said that the day of wooden bridges has passed, it is a fact that many hundreds of miles of wooden trestles, stringer, and truss bridges are still in service in the United States. This brings the discussion down to the simple stringer and trestle, illustrations of which, other than Fig. 21, are scarcely needed.

LONG'S BRIDGES

In 1830, Bvt. Lt.-Col. Stephen H. Long, U. S. Topographical Engineers, patented a truss which bore his name. He afterward modified it and was granted other patents in 1836 and 1839, "to produce lateral stiffness or inflexibility in wooden or frame bridges." This was effected by a system of lattice bracing applied either to the upper or lower chords, or to both. Concerning Colonel Long's truss Mr. Cooper remarks[35] that this is another step in simplicity and concentration of parts. Here also iron did not enter as a necessary part. Connections were made by framing the parts together or by use of wooden keys or treenails. Many bridges of this form were built, but it was never widely popular. Fig. 23, from a drawing of 1830, shows two sets of braces at the abutments below the lower chord reaching forward to the first and second panel points.

---

[35] *Transactions*, Am. Soc. C. E., Vol. XXI (July, 1889), p. 9.

The remark of Mr. Cooper applies in particular to the design of 1830. Colonel Long's later designs departed from the simplicity displayed by the first one. The use of abutment braces extending to the first and second panel points breaks the continuity of the frame as a simple truss, independent or unassisted between the bridge-seats. The term, "assisted truss," may be applied to it. The cogged cast-iron splice-blocks (or plates), which his patent drawing shows, might be used instead of wooden splice-blocks. This idea might have found favor in the days of cast iron, so to speak, but is more worthy of consideration now when steel castings with their greater strength are more readily available.

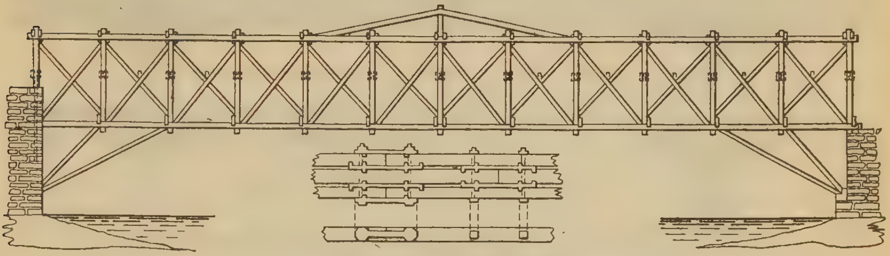

Fig. 23.—Long's Bridge.

Many rural highway bridges were built throughout the Eastern States by local carpenters, which were hybrids of the Long and Burr types, without the science of Long nor the arches of Burr. It is impossible to classify them as of any type but, due to the practical common sense of their builders and the accommodating property of wooden framing to distribute strains, these "mongrel" bridges have often given service equal to some of the widely known patented types.

The Howe Truss

In 1840, a patent was granted to William Howe, of Massachusetts, which was the basis of the Howe truss bridge so generally built throughout the country for half a century and more after the date of the patent. There were two systems of web members; that is, the diagonals ran two panels. The patent drawing also shows a secondary lower chord about 2 ft. or more above the main chord, the only function of which seems to be to carry the horizontal thrust of the end brace of one system of diagonals. It is doubtful whether there was ever a truss built with this arrangement of secondary chord and short end braces. During this season (1840), Mr. Howe, in company with Amasa Stone (1818-1883), built the great bridge over the Connecticut River, at Springfield, Mass., to carry the Western Railroad (later the Boston and Albany), which was opened for traffic the following year. This bridge had seven spans of about 190 ft., center to center of piers. The trusses had two systems of web members like the patent drawing, but the end diagonals of both systems were carried on a single-angle block at the bridge seat. (See Fig. 24.) The lower chord consisted of six sticks, running six panels of about 7 ft. each, packed close together without splices of any kind. The diagonals and rods were of uniform size throughout. In 1874, the bridge was replaced with an iron riveted lattice. It is not known to the writers that there has been another bridge built of the Howe type with webs of two systems. In 1841, Mr. Stone bought the Howe patent, formed a company, and built this type of bridge in many parts of the country.

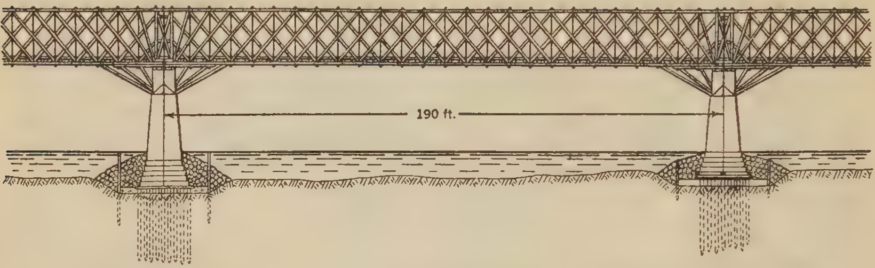

Fig. 24.—Bridge Over the Connecticut River, at Springfield, Mass.

In this type the vertical iron rods are a vital part of the web system; and the possibility of proportioning the web members for the stresses which they transmit, as well as the simplicity of the joint connections through which that transmission is effected, make this a nearly perfect type of truss. Early bridges of this type were built of white pine and, later, of spruce, and, finally, of Southern long leaf pine which, although much heavier than the other species named, is better adapted for the Howe type. The splice-clamps and keys are usually of seasoned oak. Oak angle-blocks were used for thirty years or more, but later practice considered cast iron better than wood to transmit the forces acting at the panel point. In general, Fig. 25 shows, by isometric projection, the arrangement of the members of a Howe truss, deck, railroad bridge built in 1874 over the gorge near Quechee, Vt. By cutting off the members assembled at one panel point the view discloses all the truss members and auxiliaries in the bridge, namely, the upper and lower chords, the web system of the main and the counter braces and the vertical rods, the horizontal lateral braces and rods, the vertical sway-braces, the latticed lateral system nearly the same as that proposed by Colonel Long, wooden angle-blocks, and the common arrangement of splice-clamps.

This bridge had a pair of light arches (which is unusual with this type), taking load from the truss by means of vertical rods which, passing through the needle-beams below, received whatever load the latter transferred to it. A proper splice is shown in the lower right-hand chord, and an imperfect, one-sided splice is shown on the farther chord at *D*. Each chord-stick was spliced in every fourth panel. This bridge had a clear span of about 200 ft. and a height of 24 ft., center to center of chords. There were eighteen panels, 11½ ft., center to center of verticals. The track was about 165 ft. above Ottaquechee Brook, and the bridge was carefully protected by boarding.

More recent practice improved the application of the Howe design by increasing the size of the web members and decreasing the strength of the lower chord-stick connections from the center of the truss to the ends, according to the stresses sustained. Fig. 26 shows a Howe truss substantially as built in 1889 at Morrisville, Vt., which displays these advances over the older practice. The rods in the panels next to the center are two $1\frac{3}{4}$-in. and one $1\frac{1}{4}$-in. and, in the end panel, three $2\frac{3}{8}$-in. and two $2\frac{1}{4}$-in., all upset, with gib-plates varying from 6 by $1\frac{1}{4}$ by 36 in., next to the center, to 14 by $1\frac{7}{8}$ by 50 in., at the ends. The main braces vary from three sticks, 7 by 7 in., at the center, to three sticks, 11 by 13 in., at the ends. The increase in strength of the lower chord-stick connections from end to center can be seen on the plan. Note the filler opposite the single splice-clamp in the fourth panel from the end. The cast-iron angle blocks are all of the size computed for the end panel. This practice leads to excess of iron, but saves expensive pattern-making.

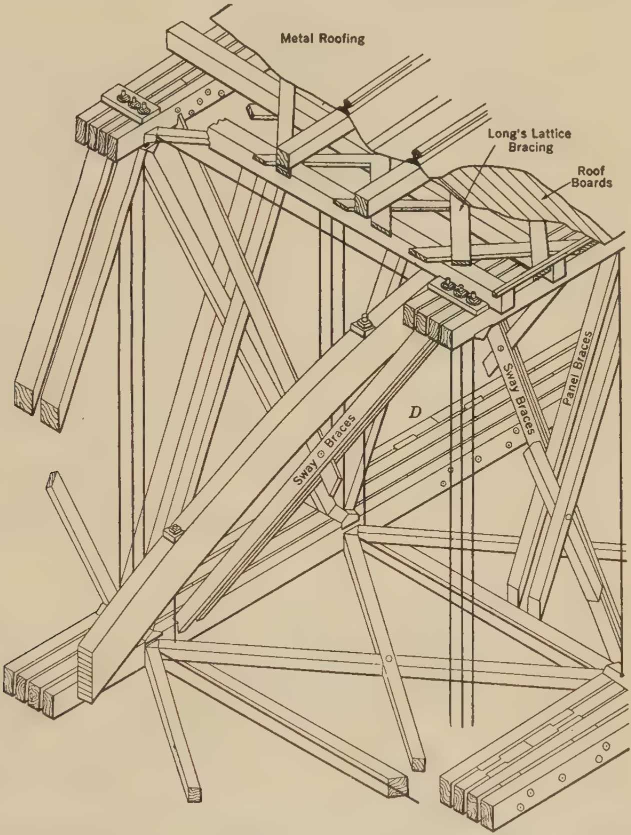

Fig. 25.—Isometric View of Howe Truss Across Ottaquechee Brook near Quechee, Vt.

For through bridges, in order to have sufficiently rigid portal-bracing and to return the side boarding to cover the end panel inside, the upper chords are extended to a connection with the end-posts which may well be in two sets with light rods between them, as shown. Howe truss bridges should be protected from the weather by roofs and side covering, the same as other types of wooden bridges. The lack of this protection has caused the premature failure of many otherwise good bridges, the life of which would have been prolonged two or three times if they had been covered as advised by the early masters of timber framing.

In 1850, a bridge was built for the Sullivan County Railroad Company, at Bellows Falls, Vt., across the Connecticut River, by George A. Parker, of Massachusetts, who, later, was Chief Engineer of the great Havre-de-Grace Bridge over the Susquehanna River in 1862. In the Bellows Falls Bridge were two 250-ft. spans of Howe trusses built with an arch on each side of each truss, Burr fashion. This bridge was replaced in 1882 by a riveted iron bridge on the same masonry that carried the wooden bridge. Arches, although sometimes built with Howe and Pratt trusses, are not indigenous with them so to speak. The south span was saved by its arches during a great freshet in 1862, when a span of the highway bridge at Charlestown was swept off and came floating down the river erect and whole, striking the railroad bridge "head on." An eye-witness states that, as the lattice-web system of the highway bridge crushed and gave way against the rugged chord of the railroad bridge, the ridge-pole of the "attacking" bridge pierced through the standing bridge, and protruded so far on the down-stream side that, as soon as the wreckage had quieted enough, men ventured out on the bridge and sawed off the overhanging stick for fear it would twist the truss. The bridge was crowded a few inches out of place on the abutment. No further damage was done.

A somewhat similar case, showing the usefulness of arches, occurred at Penacook, N. H., where a lattice bridge with an arch built on the center line of each truss (see Fig. 17) spanned the Contoocook River near its mouth. A great jam of ice, during a winter thaw, piled up against the bridge, several feet above the floor level, and sprung it 2 ft. out of line at the center; but the arches, seated on the face of the abutments, withstood the pressure, and no serious damage occurred. Except for the arches the bridge would have been pushed into the Merrimac River.

During part of the Civil War (until 1866), Mr. Parker was engaged in building the bridge for the Philadelphia, Wilmington, and Baltimore Railroad Company over the Susquehanna River between Perryville and Havre-de-Grace, Md. The superstructure was of the same type and span length as the Bellow Falls Bridge. The writers know of no other Howe truss bridges built with arches in pairs, as in these two.[36] Nicholas Powers, who had worked on the Bellows Falls Bridge, was asked by Mr. Parker to work on that at Havre-de-Grace, under a Mr. Bagley, the Superintendent. When the spans were nearly erected a tornado wrecked them, twisting an approach trestle badly out of line. Mr. Bagley was blamed and discharged. Mr. Powers prepared to go also, but the Manager asked him to take charge of straightening the approach, and finally arranged with him to superintendent the reconstruction. Mr. Powers agreed to do it for $7 per day if, to start with, he could pick fifty men. His terms were agreed to, with the promise of $500 bonus if he finished the bridge without accident. Mr. Powers had his 16-year old son as Assistant, and, at times, had 400 men employed on the work. Meanwhile, the haying season was on at the home farm in Vermont. To the urgent letters from his wife to come home and secure the hay crop, he replied by sending money to hire the needed help. The bridge was finished sometime in November, a celebration was planned for the dedication, and a picture was to be taken of the bridge crew with Mr. Powers in the center; but he had promised his wife that he and their son would be home for Thanksgiving; he kept the promise and the picture was taken without him.

---

[36] A good wood engraving of two of the twelve spans of the Havre-de-Grace Bridge resting on stone piers and abutments, may be seen in Appleton's Cyclopedia, Vol. III, p. 273, pub. in 1873.

The great popularity of the Howe truss was well deserved. Many hundreds were built in all sections of the United States and Canada. However, this type cannot be classed strictly with wooden bridges, inasmuch as it uses iron rods for web-tension members—one of the four essential elements of the open framed truss. The development of railroads at the time of Mr. Howe's patent (1840), gave a great impetus to the manufacture of iron, and made it possible to procure round rods in quantity. The type is really intermediate between wooden and iron bridges.

Iron angle-blocks were sometimes cast with tubes extending through the chord, as in Piper's patent of 1867, for the double purpose of furnishing resistance to horizontal thrust by being notched into the chord-sticks; and, also, by contact with the gib-plates, to resist the vertical pull of the rods. Some writers specified that the tubes be made short enough to allow for shrinkage of the chord timbers; but such shrinkage may be more or less than the allowance; and it is best to provide sufficient hold on the chord itself for the horizontal thrust, and also gib-plates large enough to prevent side-grain crushing of the chords. If the tubes and gib-plates come in contact, the chord is generally loose and does not properly support the angle-block. Hence, it is best to omit the tubes and design the angle-blocks and gib-plates to do their part without them. Unless the cast-iron angle blocks are unusually large, it is not profitable to attempt to save metal by coring the central part, although this is the practice of some designers.

Colonel Long's patent of 1830 claims a cast-iron splice plate for the chord-sticks. A modification of this as a steel casting for splicing the chord-sticks in Howe trusses is well worthy of attention. The plate can carry four cogs instead of two, as shown by the wooden splice, and can act as a key by having cogs on both sides and also as a spacer if rests are cast to bring the plate in the center between the spacing of the chord-sticks. The principal difficulty in the use of these plates is in boring the holes if the timber and plates are in place; but it can be done by the skillful use of a ship-auger type of bit (see Fig. 23).

Designing the angle-block of the Howe truss involved the brace-in-panel problem, which is to have the squared ends of the timber brace and the

inclined bearing surface of the angle-block fitted so that the center line of the brace and the vertical axis of the rod will meet on the center line of the chord. This involved also the camber to be given to the truss. In theory, it is a problem in higher mathematics. In practice, each builder usually had his own rule, and the best one was to lay out a panel full size and cut a template for the brace, leaving just such an angle-block as he wanted, and then, for camber, cut his counters a little short, the amount determined by his experience. The camber was given partly for the sake of appearance. Optically, to some observers, a truly horizontal chord might appear to have a slight sag. Even an actual slight sag was of no consequence if it did not increase so as to indicate over-strain of the truss. However, there is a good reason for camber, because of the compressibility of wood and the imperfection of hand-made joints.

Keys and joint clamps should be framed with bearing surfaces and notches cut with a slight draft so as to require driving to place when erected (see details in Fig. 26) and the depth of the notches should be such that the end fiber resistance to the compressive strength at the notch should be equal theoretically to the tensile resistance of the uncut cross-section of the necks of the clamps. The notch must be made far enough back from the end of the chord-stick so that the lengthwise shearing resistance of the softer wood shall be so adjusted to the pull that a slab will not split off between the notch and the end. This is usually the weakest part of the connection. Many splices have failed by such splitting. Almost invariably, in old bridges of this type, outside sticks have only their inner side clamped, as shown at *D* in Fig. 25; and all the clamp bolts are in the head of the clamp, leaving the ends of chord-sticks free to bend outward, which increases the tendency to split off at the notch. The builders were very loath to bore through the neck of the clamps.

THE PRATT TRUSS

A patent was granted in April, 1844, to the late Thomas W. Pratt, M. Am. Soc. C. E., and Caleb Pratt, the claims for which are indicated in a drawing of which Fig. 27 is a copy. In this patent the attempt was made to

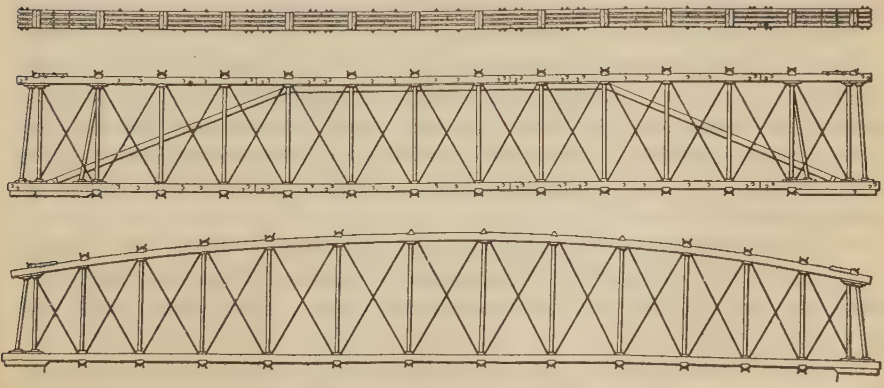

FIG. 27.—PRATT TRUSS, AS PATENTED IN 1844.

use timber in the simplest and most efficient manner in the web members by confining it to the verticals. The advantage of doing this, however, is over-matched by the longer rods required than in the Howe truss, and the awkward angle-blocks needed for these diagonals. For all metal trusses, however, the Pratt truss is ideal.

For railroads, the continuing increase in weight of equipment and loads has kept the problem of strengthening bridges before engineers. For the early Howe and Pratt types it has been found that the tension rods are the weakest single feature. In the Howe truss, yoking on additional rods is an easy remedy; furthermore, reinforcement is easily applied to the timber diagonals. In the Pratt truss, this is far more difficult; but the Pratt truss permits curved upper chords, as shown in the lower drawing, and this is desirable for long spans. Evidently, in the Howe type, curvature of the upper chord would introduce complications in making proper seats for the varying lengths and inclinations of the diagonals.

In the parallel-chord truss the king brace and strain-beam shown in the upper drawing of Fig. 27 is a reversion to the European practice more than a century old in Pratt's time. In a panel truss it befuddles computation of web stresses and is a faulty device on several counts for assisting a truss which should be designed to be strong enough without it.

The activities of the Childs Brothers in building bridges, especially for the New England railroads when these were young, has been noted herein previously. The drawing accompanying the patent granted to Horace Childs in August, 1846, indicates an attempt to combine the Howe and Pratt types. It is defective in omitting counter-rods in the middle panels, and peculiar because of an awkward attachment of the main braces by a joint bolt passing through the chords and the angle-block, and up into the brace, which was a crude method of making the main braces act as counters. The Childs Brothers built many bridges of various types, among them the Granite Street Bridge, in Manchester, N. H., over the Merrimac River, in 1862, and one over the same river in Hooksett, N. H., in 1858.

TOLL BRIDGES

Incidentally, the term, "toll bridge," has been applied to several of the old bridges previously described. Some may not realize that, at first, with possibly a rare exception, all bridges were built by private initiative under charters granted by the State. The charters specified the tolls to be charged, subject to change only by decree of the Court. In populous districts the interruption of travel at the toll-gates became so inconvenient and annoying that counties and towns bought the charter rights and gradually made the bridges "free."

Of thirty bridges built across the Connecticut River between New Hampshire and Vermont, north of Massachusetts, beginning in 1785, twenty-six were chartered by law and operated as toll-bridges. At present (1932), all but two are free.

In this Twentieth Century, comes a reversion to the toll system, or policy. In the great metropolitan districts, and at points where wide streams must be crossed by trunk-line highways, the cost of erecting and maintaining the huge and lengthy structures, with capacity sufficient for the enormous volumes of light and heavy traffic, is too great to be collected by general taxation. It must be retrieved by toll charges upon those who use the facilities.

WOODEN DRAW-BRIDGES

The roads over the broad estuaries and tidal streams mentioned under "American Timber Bridges," invariably required openings for the passage of water craft. In pioneer days, land transport was difficult, and it was desirable to get water-borne traffic as far inland as high tide would float the small vessels then used. Invariably, draw-bridges called "tip-ups" were built in such cases. They were narrow so that four oak logs sufficed for stringers. Crooked trees were selected with large butts which helped as counterweights. These logs were 12 to 15 ft. longer than the width of the channel to be spanned. The stringer portion over the opening was hewn as small as practicable. An oak log firmly framed to the stringers, with rounded ends to turn as trunnions, served the purpose of a hinge. Chain guys passing over sheaves at the top of a gallows frame spanning the roadway, actuated by hand windlasses, raised the free end of the bridge when desired. If the opening was too wide for a single leaf, two were used meeting at the center, with a toggle arrangement to hold them in grade under passing loads.

These bridges required the lifting of a section of the plank over the hinge, to allow the draw stringers to turn up. This is simple in a highway floor; but with the introduction of railroads, difficulty developed in lifting the rails and their supports, so that a swing bridge of the type called the "A-frame swing-draw," was adopted. The stringers of this bridge were framed to rest at the heel—when swinging—on a pivot under the center of the track, at a distance back from the channel cap. The head of the A-frame was vertically over the heel pivot when hauled backward for raising the swing end of the bridge. The guy rods running from the head of the frame to the needle-beam under the stringers were held apart for side clearance of the train by a spreader-beam high enough above the track for proper head clearance. A hauling-off beam attached by a pin to the side of the bridge carried a rack into which a pinion, operated by a hand-crank on shore, meshed to swing the bridge off and on,[37] the same as indicated by the illustrations referred to under "The Jackknife Draw-Bridge."

The Jackknife Draw-Bridge.—The A-frame draw was awkward to arrange for in some locations. When the Gloucester Branch of the Eastern Railroad was built in 1845, a draw-bridge of some other type was required for the entrance of the little harbor basin at Manchester, Mass. Joseph Ross (1822-1903), a young mechanic of Ipswich, Mass., and Samuel Ashburner, a draftsman, engaged on the work, "got their heads together" and designed what was afterward called the jackknife type of draw-bridge. This important development has been adequately described elsewhere.[38]

A Unique Bridge

A bridge of singular distinction, the pride of Schoharie County, New York, deserves special mention. The location is North Blenheim, on Schoharie Creek. (See Fig. 20.) Erected and long maintained as a toll bridge, it was finally taken over by the town which has carefully kept it in prime condition. The record states that the "contract to design and erect the bridge was awarded to Nick Powers, a Vermont Yankee who built many such structures," and that "the bridge was not built over the stream as many would believe, but was constructed piece by piece, back of the present village near the site, and there set up to make certain that every part was perfected before erection over the river was attempted." While this was being done, the masons built the abutments. The material is native oak and pine. The unique feature is the single arch, framed and built on the center line of the middle truss, and this truss extends upward 6 or 7 ft. higher than the side trusses, so that its upper chord forms the ridge of the roof. If the floor timbers extended across the entire 26 ft. of the width, thus serving both roadways, they would contribute greatly to the stiffness and stability of the entire structure.

From available evidence it seems likely that the posts and diagonals were framed to pass through the chords as in Long's design. It has the unusual span of 228 ft., but this gives no distinction over bridges already considered. It can scarcely be classified or correlated with any other type of bridge that has come within the knowledge of the writers. Built in 1855, it is claimed to be quite serviceable for the traffic which it now carries after seventy-six years of usefulness; but the County Officials decided that it must be replaced by a modern concrete structure. However, according to later report, the bridge will be maintained as a local antique.

Retrieving Weak and Injured Bridges

It may be said that it is more feasible to strengthen a wooden bridge in a satisfactory manner than one of metal or masonry; and that the deficiency in the strength of a bridge scientifically designed is more difficult to remedy than in one built by guess, when one member is proportionately weaker than the bridge as a whole. Timber bridges are subject to decay and various accidents, and may develop structural weakness of parts, all of which require timely attention.

First-aid or emergency treatment involves, generally, the setting of trestle bents under the bridge. Where these cannot be permanent, many bridges may be strengthened by the addition of plank arches inside the truss, if side clearance permits. Vertical hanger rods that pass through needle-beams hung below the chords carry the bridge load to the arches.

Lattice bridges are sometimes struck by running ice during spring freshets, and the lattice plank projecting below the lower chord may be broken off, so as to weaken, seriously, the power of the lower chord to carry the floor-beam load. Hanging the lower to the second chord by simple rods or yokes is the usual remedy.

If bridges tend to get out of line, as some do, they are guyed with wire ropes or rods to well-fixed bolts or other permanent anchorage on the banks of the stream. Decayed or broken parts may sometimes be renewed in kind. A common fault in all types is insufficient strength in the floor system. This calls for additional floor-beams or stringers, or both.

Lower chord-stick connections in all types are often deplorably weak in panels near the middle of the span. Fig. 25 at *D* shows a defect exceedingly common. The pull of the single clamp tends to throw the end of the stick outward, which greatly aggravates the tendency of the head to split at the notch. The remedy for this is an additional clamp cogged in and bolted on the outside; or, if split, by various types of iron couplings shown in Fig. 28, or in Fig. 16, for use in a 4-in. plank. The couplings can be extended to strengthen the central section for a length of, say, 40 ft., in lattice bridges, using loop ends at the gibs and right and left-hand threads for a turnbuckle at the center. Multiple rods can be used in this manner without trouble. Another favorite method is to attach an auxiliary stick to the side of the chord, connected with effective keys and large bolts or pipe drift-pins.

FIG. 28.—REINFORCING COUPLINGS.

The tension rods in Howe and Pratt trusses are frequently found to be deficient in strength. Reinforcement is made by yoking a pair of rods to the truss with gib-plates of wood or iron across the chords, as near the panel points as possible. Reinforcement is more difficult in the Pratt than in the Howe trusses on account of fitting the gib-blocks to resist the horizontal pull of the inclined rods. The web rods in most of the older bridges were not upset, but facilities for upsetting are now such that its neglect in the long rods required for through railroad bridges is inexcusable.

The bridge builder cannot be too careful as to designing the bolted and spliced joints, in order to equate properly the stress and resistance where the parts come together. Manifestly, the tensile strength of coupling bolts and bars, the beam strength of gib-bars and bolts, the compressive resistance of cut-fiber surface and side grain of timber, and the tensile strength of the uncut section of the pieces united or joined, are all factors to be considered. Adjustment should be made so as to secure, with reasonable accuracy, equality of action and reaction throughout the combination.

Bridge Curiosities and Atrocities.—An interesting sidelight of the subject of timber bridges is the example, now and then, of the effect of ignorance and carelessness on essential details of construction. Three letters on this subject were published[39] in 1893.

SUMMARY

Reviewing in succession the advancing phases of this history, the writers have discussed the twisted-vine-cable bridge, in various adaptations to existing conditions, as the natural conception of primitive and early barbarian people. Then, in less barbarous and more semi-civilized times, the overhanging timber cantilever structure followed as an extension of the plain crib-work and log stringer.

Around the Mediterranean Sea, during the period of the colonizing and commercial activities of the Phœnicians and Greeks, there seemed to be little thought of bridges. Land commerce was borne by camels across the deserts, and by other pack animals in more settled regions. Wheeled vehicles were, for the most part, war chariots. The then abundant forests provided the timber for the ships sent forth from Tyre and Sidon. Ezekiel, the seer, wrote that the ship planks were made from fir trees, the masts from cedars of Lebanon, and the long oars from the oaks of Bashan.[40] A greater requisition on the forests was made later when the Greeks, Carthaginians, Persians, and Romans, in their long-prowed biremes and tiremes, fought the historic naval battles for the mastery of the inland sea.

It is conceded now that the conception of the arch as an architectural feature in masonry structures originated in the Near, or Farther, East. Quite recently archæologists have uncovered a tomb in Ur of the Chaldees, entered under a true arch of burnt brick. This is said to be 5 000 years old. In Europe, the extensive use of timber for bridges doubtless began when Rome first started to develop its expanding system of military and post roads. Cæsar's Rhine Bridge is a fine type of emergency bridge which would be creditable to a modern engineer. That the early Roman timber bridges embodied the preference for the semi-circular arch appears from the description of Trajan's Danube Bridge. After the long lapse of the Dark Ages, when the Renaissance brought new interest in public works, the flat arch became the standard type. It was expressed in open framing and bracing, such as proposed by Palladio; or solid timber arches, all usually with nearly level floors and side parapets, with no protection from the weather. The ponderous framing of some Swiss bridges like that at Schaffhausen, with their awkward lengthy bracing, found little acceptance. The low arch types, usually examples of good architecture as well as good engineering, prevailed during the Seventeenth and Eighteenth Centuries, until the later European timber bridges were displaced, during the Eighteenth and Nineteenth Centuries, by the splendid masonry bridges which stand as enduring monuments to distinguished engineers.

[40] Ezekiel, XXVII, 5 and 6. About the Seventh Century B. C.

Since the aboriginal Americans had little use for products of the forest, the earlier American settlers along the coast had plenty of timber for pile and stringer bridges. Then Enoch Hale made courageous utilization of the magnificent white pine timber at his disposal for bridging the Connecticut River at the Bellows Falls gorge. Following him, the skillful and resourceful Timothy Palmer, and the ingenious and conscientious Lewis Wernwag built their great flat arches of wood somewhat stiffened by truss framework on top. Their insistence on careful protection from the weather inaugurated the distinctly American type of covered "through" bridge. In the first decade of the Nineteenth Centry, Theodore Burr brought out his idea of combining arches springing from the face of the masonry below the bridge seat, with a real truss, the lower chords of which carried the floor. This type of truss perhaps inadvertently on the part of Mr. Burr inaugurated a new era in bridge building, rendering it possible to trace the actions of loads from the point of their application to the supporting masonry.

At the end of the second decade Town brought out the lattice type; and, at the end of the third decade—in 1830—Colonel Long patented his design. These three types, Burr's, Town's, and Long's, are the only important ones, extensively used, that were practically constructed wholly of wood. From 1830, the building of railroads gave a great impetus to the building of bridges; and, in 1840, the Howe type with iron-rod vertical web members, became a favorite; and, in the next decade, the Pratt type, with iron-rod diagonals and timber verticals, soon led to iron lower chords; and then followed the so-called combination bridge interspersed with the early all-iron structures.

It is interesting to note the growth of the use of iron in bridge building. The building of clipper ships along the New England Coast up to the middle of the Nineteenth Century developed there the art of framing heavy timbers, the fastenings of which were made chiefly by treenails ("trunnels"). The iron used was fashioned by the smiths in the shipyards. Timothy Palmer, trained in those yards, used some slotted iron bolts, tightened by keys, as can be detected in Fig. 11. Use of threaded bolts became general afterward. Town used treenails only, but later practice in his type of bridge prescribes bolts freely, and rods where supplementary arches are used. In 1840, Howe made iron-rod verticals the basis of his claim, while Pratt, in 1850, extended their function as diagonals, and also made the curved upper chord a feature. The combination type called for iron diagonals and lower chords with compression members of timber. As early as 1840 all-iron bridges were built with cast-iron compression and wrought-iron tension members. The ingenious and scientific Squire Whipple, Hon. M. Am. Soc. C. E., enters the field here, using this combination of cast and wrought iron successfully for many years. In 1859, Howard Carroll built the first all wrought-iron bridge for railroad use. It was a riveted lattice truss, and the contest between the riveted and pin-connected types was on. In the last decade of the Nineteenth Century steel took the place of iron as the best material for bridges; and now, ninety years after Howe's introduction of iron as an integral part of the truss, other alloys of steel are coming to replace carbon steel in the art.

ACKNOWLEDGMENTS

Special acknowledgment is due to John W. Storrs, M. Am. Soc. C. E., Consulting Engineer, Concord, N. H., for co-operation in research and for valuable information freely given. Others to whom the thanks of the writers are due are, Frank B. Rowell, Research Engineer, Boston and Maine Railroad Company; Lyman S. Hayes, Town Clerk, Rockingham, Vt.; and Mrs. Mary N. Bolles, Bellows Falls, Vt. Several other correspondents have contributed important data without which the history would have been less complete.

DISCUSSION

Henry B. Seaman,[41] M. Am. Soc. C. E. (by letter).—This valuable paper is not merely a history of wooden bridges; it is practically a treatise on the design of wooden bridges of the more recent types. The Howe truss will be in vogue in timber countries for many years to come. The recent tendency toward iron bridges is partly the result of heavier engine loading; but it is due more especially to the increased price of timber, which would have less effect in countries where the timber is ready at hand.

Fifty years ago there were still many Howe truss bridges on the Pennsylvania Railroad. Although they were really combination bridges of wood and iron, they were classed as wooden bridges, and if iron was used unnecessarily it was considered an indignity to the wooden truss. Cast-iron angle blocks and wrought-iron tension rods were a regular part of the construction. The chord splices were of oak and were compactly bolted in place. In proportioning the splice, the area of the split section to that in the end thrust bearing was in a fixed ratio. Long spans (180 ft.), which still remained in service, had arch ribs on each side of the truss, which extended down below the chord to the face of the abutment, on skew-backs.

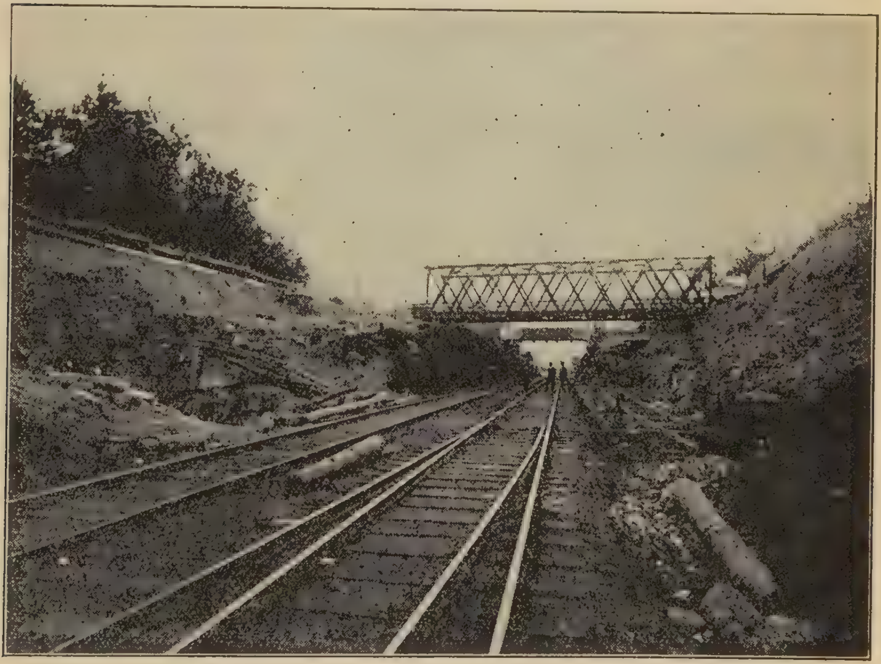

Fig. 29.—Timber Howe Truss, Mount Vernon, N. Y., 1893.

---

[41] Cons. Engr., Brooklyn, N. Y.

On the Erie Railroad, about ten years later, there were many Howe truss bridges of shorter span, but without the arch rib. Since the Railroad Company was avoiding the appointment of a Receiver, the bridges were used to their ultimate of safety and were badly "hog-backed" before removal. They were tested at the critical joints by the use of a small auger to ascertain the condition of the interior wood, and the holes thus made were then filled tightly with plugs. It was the saying that "a wooden bridge never falls down," which was, of course, a dangerous doctrine; but it received apparent corroboration when the Market Street Bridge, in Philadelphia, Pa., was removed, and was found to have been literally punk.

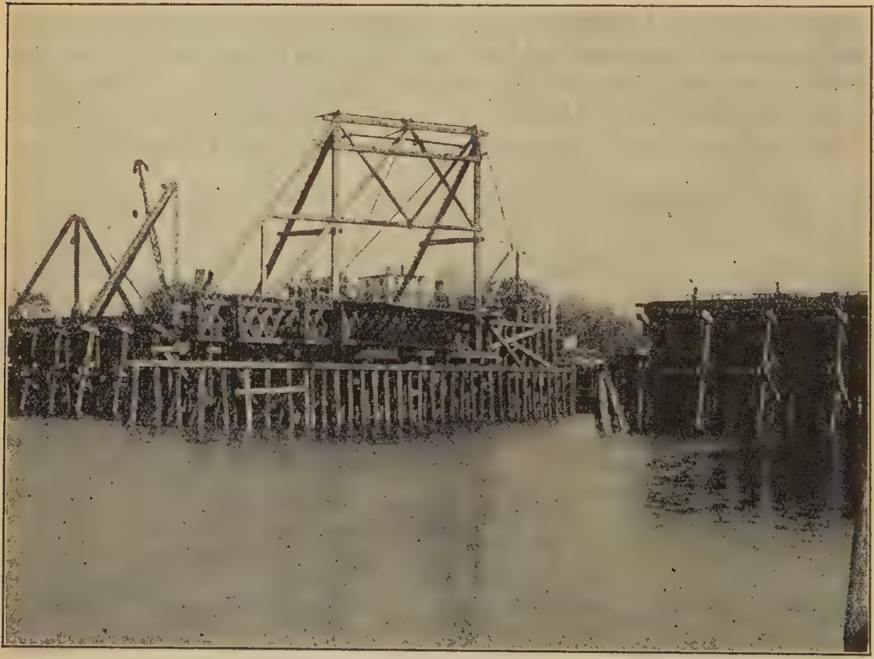

FIG. 30.—TYPICAL JACK-KNIFE DRAWBRIDGE, WESTPORT, CONN., 1905

About 1893, the writer had occasion to design and construct the overhead Howe truss bridge shown in Fig. 29, for a temporary crossing of the New York, New Haven and Hartford Railroad, at Mount Vernon, N. Y., and found no difficulty in obtaining trained carpenters to execute the work. It was of simple design, with oak angle blocks, a complete upper lateral system, and knee-braces only at the portals.

More could be written on the subject of the jack-knife draw-bridge. This is still a useful type for temporary purposes. While re-constructing the main-line bridges of the New Haven Railroad at Cos Cob and at Westport, Conn., in 1905, two such bridges, double-tracked, were constructed by the writer, and served well for main-line service during the reconstruction. One of them is shown in Fig. 30. These jack-knife draw-spans were part of the temporary by-pass trestles. For satisfactory operation of the draw-span, it is important that the gallows-frame be inflexible, and that the pile bents from which the trusses swing, be rigidly braced against movement.

JASPER O. DRAFFIN,[42] M. AM. SOC. C. E. (by letter).—Timber bridges of the type discussed in this paper are fast disappearing, particularly in Vermont where a large number have been replaced within the last ten years and especially since the flood of 1927. The writer is particularly interested in one of the bridges described, the Enoch Hale Bridge, at Bellows Falls, Vt., or the first bridge over the Connecticut River. The latest successor to this primitive bridge is a two-span, reinforced concrete arch built in 1930.

That this early bridge was considered important is shown by the account mentioned by the authors,[43] which reports that Enoch Hale "has just built" a two-span bridge, across the Connecticut River at the "Great Falls," 360 ft. long and 60 ft. above high water. It was believed to be the most elegant, the strongest, and one of the most useful bridges in America. The item went on record that while the work of building it was dangerous, the only casualties were the death of a young man who fell on the rocks in the river, and a slight injury to Colonel Hale.

The main route between Boston, Mass., and Montreal, Que., Canada, passed over a turnpike road through Keene, N. H., crossed the Connecticut River at Bellows Falls, and continued across the Green Mountains to Rutland and Burlington, Vt., and thence to Montreal by Lake Champlain. Consequently, it was an important artery of travel and transportation at that time and the Hale Bridge was a vital link in it. The reason for the selection of this place for the construction of the bridge was that the river is narrow (300 to 400 ft. wide), passing through a rocky gorge with a ledge in the middle, on which a center pier could be placed. A more favorable site for a bridge can scarcely be imagined; but not only was the location desirable from an engineering point of view, it had a considerable reputation for scenic beauty.

A question has been raised concerning the replacement of the original Hale Bridge. This arose mainly because Timothy Dwight stated[44] that, "in 1803 [the year of his first visit to Bellows Falls] the bridge erected by Colonel Hale * * * had been taken down and a new one built." He does not say that the replacement took place in 1803, but merely that it had been done by that time. In an earlier paragraph, he states that the original bridge was standing in 1797. Therefore, if his account is correct, a new bridge was built between 1797 and 1803 to replace the one built by Colonel Hale. Some doubt of the correctness of the Dwight account has been expressed, partly because there did not seem to be any local tradition of the replacement. However, there is a record that the owner of the bridge, a Mr. Guier (or Geyer), was trying to raise money by mortgaging his property at about the time of the supposed second building of the bridge. The bridge built by Colonel Hale has been described as a combination of arch and truss and neither the first bridge (see Fig. 8), nor the second one was of this type; but the description of the second bridge by Timothy Dwight would lead one to conclude that it was of the arch type, since he described it as "an obtuse arch." Taking into account all the uncertainties and the short time between the building of the first bridge and its replacement or rebuilding, it seems reasonable to conclude that the original bridge was not replaced in its entirety by a new bridge, but that it was merely closed to traffic and extensively repaired between 1797 and 1803. In the beginning of his search for information, the writer wished to believe that there was an entire replacement of the bridge, but the evidence obtained thus far does not warrant such a conclusion.

---

[42] Assoc. Prof., Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.

[43] *The Massachusetts Spy,* February 10, 1785.

[44] "Travels in New England and New York," 1803.

The reconstructed bridge lasted until 1840 when it was replaced by what was known locally as the "Tucker Toll Bridge," shown in Fig. 18, and which was of the covered lattice timber type with sidewalks on the outside of each truss. It was placed 15 ft. higher than the Hale Bridge which was used during the construction of the new one, after which the old bridge was cut away and allowed to fall into the river.

E. K. Morse,[45] M. Am. Soc. C. E. (by letter).—It is refreshing to read something that is not buried in a mass of intricate calculations that are known only to the author. Several facts have not been mentioned in this paper, namely, that many of the old wooden bridges, especially those constructed by Burr, were built of sized white pine, free of knots, adzed into shape, and then hand-surfaced on four sides. This was especially true in the Burr Arch Bridge across the Allegheny River at Ninth Street, in Pittsburgh, Pa. (which the writer contracted to remove in 1890-91), and also in a bridge of the same design built by Burr at Saltsburg, Pa., across the Kiskiminetas River.

In inspecting the bridge at Saltsburg some years ago, the writer found the name of one of the carpenters who evidently had planed the beautifully shaped and finished members of the arches. The man had engraved his name in the top of one of the arches which was just as bright and as clear as the year it was erected. All the timbers going into these bridges were seasoned from two to four years before being placed in position, which accounts for the accurate work and the condition of the bridges after years of heavy travel. On the Ninth Street Bridge there was not an open joint on any of the spans, averaging from 178 to 210 ft, center to center of skew-backs. The white oak flooring, like the white pine, was seasoned in the old-fashioned way and surfaced on all four sides. Teams and wagons passing over the floor moved so smoothly that the edges were not frayed. In practically all the bridges that were erected by Burr, the floors were originally laid dust-proof and because they were not exposed to the elements, they remained intact for many years.

In taking down the old Ninth Street Bridge, heavy vehicle and foot travel had to be maintained and, in order to facilitate erection, the roof was removed, the trusses were cut to the line of the arch, and $1\frac{1}{2}$-in. bolts were placed through the edge, and the verticals supporting the floor system clamped tightly to the arches wherever they showed signs of weakness. In order to prevent excessive vibration, a two-post tower with sway-bracing was erected at the center of the arches. There was considerable vibration in the arches when they were cut loose from the floor system and the tower was removed, but when 1½-in. manila rope was connected to the top of each arch and it was attempted to pull them over and dump them into the river, they yielded readily for about 3 or 4 ft and then resisted even the 5 tons of horizontal pull that was put on them, and eventually had to be removed panel by panel.

---

[45] Engr. Member, Water and Power Resources Board of Pennsylvania, Pittsburgh, Pa.

It was found that the members in all the arches had completely lost their fiber to the extent that it was almost impossible to cut one of these timber arches with an axe. It was as difficult to lift a chip from one of these white pine timbers as it is with a red gum or green sycamore. The timbers were bright. During the erection of the new bridge, they supported a load three or four times as great as that for which they were designed and, in no case, did any member of the arches show any sign of weakness before, during, or after being taken down. A match factory in Chicago, Ill., had bought the timber in the white pine arches, and needless to say the contract was cancelled when it was discovered that white pine which is so easy to chop and so beautiful to work, had become as tough as gum.

JOHN W. STORRS,[46] M. AM. SOC. C. E. (by letter).—This paper is not only interesting and informative, but instructive, and must have required much thought, research, and investigation.

Old wooden bridges have recently been the subject of a number of brochures. Many people are showing an interest in these structures. As an exemplification, there was an unique service at the site of an 82-year old bridge in the Town of Boscawen, N. H., on the afternoon of December 3, 1932. This is a covered bridge of the Burr type with arches, and it spans the Contoocook River. It has been in constant use since 1850. Repairs have been completed recently, and it will do service for a long term of years to come.

The bridge at Woodsville (in the Town of Haverhill, N. H.) built in 1828, and the one in Bath Village built in 1832, are still in service and apparently taking care of the traffic in a satisfactory manner.

The writer would be one of the last to cast any reflections, to find fault with or to criticize the earlier American builders of bridges. They were limited as to means and material; had little to go by except trial and experience. Some of the so-called hybrid or mongrel bridges did, or have done, extraordinary and remarkable service, and the constructors and bridge carpenters of those days "did the best they could; angels could do no more."

C. J. HOGUE,[47] M. AM. SOC. C. E. (by letter).—This paper is one of great historical and informative interest and value, at least to one connected with the timber industry, and the writer hopes that it may be to others, as well.

---

[46] Cons. Engr., Concord, N. H.

[47] Engr., West Coast Lumbermen's Assoc., Inc., Seattle, Wash.

It brings the history and practice in wood bridges to date, and the writer believes that the present is the eve of a fourth era in wood bridge design and construction, which will be of even greater interest and importance, from both engineering and architectural viewpoints, than the three recorded in the paper.

Temporarily, bridge design and construction in wood have been somewhat eclipsed by other materials. These materials have been new; wood construction has been old. They have been replete with new technical studies and developments; wood technology, old as it is, has lacked definite information on some points.

To-day, as not for many years, the bridge designer is faced with the necessity for the utmost economy and, probably as never before, with the question of the length of useful life and early obsolescence. A timber supply is amply available, recent research has established authoritative information on most points in question, new methods of framing have been developed, and treated timber offers material of economic permanence, ease of remodeling, low cost of removal, and salvage value on removal.

During recent years, the Forest Products Laboratory, of the U. S. Forest Service, at Madison, Wis., has published the results of technical studies which have taken the mystery and variance from the calculation of the bearing strength of wood posts, of bearing on wood at various angles to the grain, of the bearing strength of bolts on wood, of the calculation of shear in wood beams and stringers, and of the basic principles of calculating the strength of laminated wood beams and posts. The ring dowel connector, developed in Germany during recent years, opens a vast new field of economy and flexibility in wood framing.

It has been shown by experience that the durable life of treated timber may be assumed safely at forty years or more; it seems to be the consensus of opinion of bridge engineers that the useful life of a bridge in these times of rapid change may not be assumed safely at more than twenty to twenty-five years, often even less, due to early change in location.

The public has been taught to expect beauty as well as utility in its bridge structures. During 1932 a number of bridges of appealing architectural character, with little increase in cost, have been built in Oregon.[48] Such framing connectors as the ring dowel open the field for wood bridge construction to long-span arches and arched trusses of imposing size and appearance. The writer believes that a new chapter in wood bridge construction is about to be written.

William A. Oliver,[49] Assoc. M. Am. Soc. C. E. (by letter).—The reading of this paper has been a pleasure and an inspiration. The education of an engineer is not complete until he has become acquainted with the work of the giants who have gone before him. It is through such efforts as the one under discussion that this part of an engineering training is obtained.

---

[48] *Civil Engineering*, September, 1932, Vol. 2, No. 9, p. 549.

[49] Urbana, Ill.

In their "Synopsis," the authors write, "but it will appear that, where timber is plentiful * * * wooden bridges still have 'a reason to be.'" Later, they state (see "Stringer Bridges"), "although it can be said that the day of wooden bridges has passed, it is a fact that many hundreds of miles of wooden trestles, stringer, and truss bridges are still in service in the United States." It is not entirely clear just what the authors' conclusion is regarding the present adaptability and economy of timber bridges. The writer would like to discuss the paper briefly from this point of view.

One of the important objections to timber bridges and structures generally has been the so-called "lack of permanency." The writer does not believe that the facts justify this idea. By proper maintenance a timber bridge may be just as permanent as a bridge built of some other material. For centuries, and by consistent and precise maintenance, the Japanese have made their timber bridges perpetual. Numerous examples of timber bridges several decades old can be found in the United States, and many of these bridges have had only ordinary care during these years of constant use. Certainly fifty years is a long life for any ordinary bridge of any material in the United States. Some examples of present-day wooden bridges are briefly discussed in the following paragraphs.

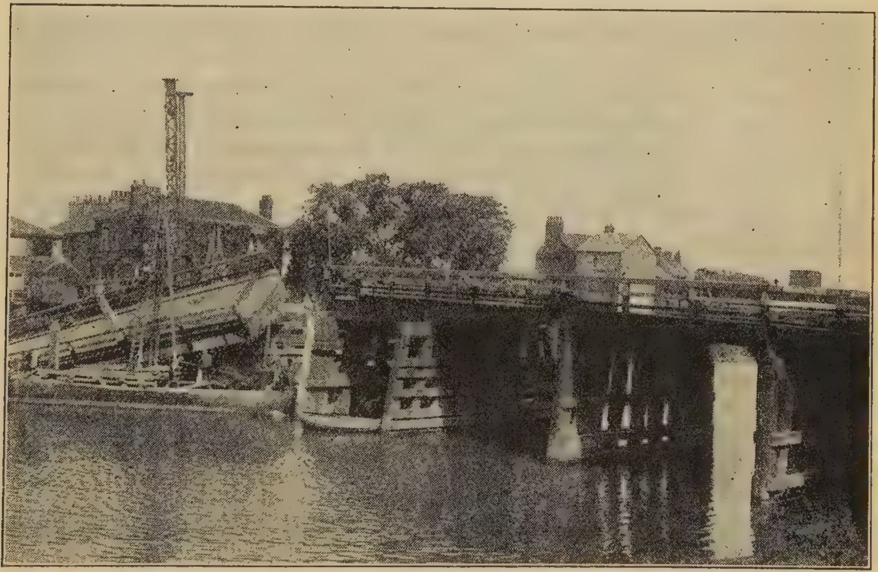

FIG. 31.—SELBY BRIDGE OVER THE RIVER OUSE IN YORKSHIRE, ENGLAND.

According to Mr. E. Jervoise,[50] Selby Bridge over the River Ouse, in Yorkshire, is probably the oldest timber bridge in England. It was built in 1790 and is still in use (1933). The bridge has a swing section which, in Fig. 31, is shown thrown from its pivot. Mr. Jervoise states that through this mishap the bridge was out of use for some time.

---

[50] Ancient Bridges of England Series, Architectural Press, Westminster, S. W., London, England.

Of course, modern examples of wooden bridges are plentiful on the West Coast of the United States, but, in 1932, the State of Ohio found it expedient to build ninety-three timber highway bridges. Most of these structures were of a simple trestle type, built of timber produced in the State. All material was impregnated with preservative, all framing being done in advance of treatment. It is interesting to know that a mid-Western State had timber in this quantity available for use, and that one of the more progressive States did find it economical to adopt such an elaborate program of timber bridge construction.

One of the earliest of materials of construction, timber has been developed for structural purposes by "rule-of-thumb" methods. Due to the inertia that these "rule-of-thumb" methods obtained through the years, it has been difficult to make the ordinary timber user appreciate the fact that greater economy as well as strength could be obtained through a more scientific use of the material. However, through the efforts of the various lumber manufacturers' associations and the work of the materials testing laboratories, this difficulty is gradually being overcome and the general trade is evincing more and more interest in researches in the use of timber. Many examples of present-day research could be given as examples of what is being done along these lines. As far as the testing laboratory is concerned timber is almost an ideal material, conforming beautifully with the accepted theories of mechanics.

Referring to the work of Messrs. Brangwen and Sparrow,[14] the authors state in their discussion of Roman bridges, that very little is known of the construction of Pons Sublicius, "hallowed by traditions." A longitudinal elevation and a cross-section of this bridge has been published[51] by Mr. H. G. Tyrell. The writer wonders whether the authors question the authenticity of this illustration.

Philip G. Laurson,[52] M. Am. Soc. C. E. (by letter).—The authors have contributed a paper of great value to civil engineers who are interested in bridges. Much of the information is not available elsewhere.

It is natural and proper to emphasize the American developments as the authors have done. It is true, however, that wooden bridges were used in Europe a century ago to a greater extent than is commonly realized.

The *Minutes of Proceedings* of the Institution of Civil Engineers of Great Britain, and other European engineering publications, contain numerous descriptions of wooden railway and highway bridges. In 1846, John Rennie, in his Presidential Address, reviewed the developments in all branches of Civil Engineering, including wooden bridges. He reported at that time[53] that the trussed system had been applied with considerable success in some well-constructed bridges across the Tyne River and in several other places. The system of combining small curved pieces of timber connected in the form of an arch, adapted for large spans, was first introduced by C. F. Wiebeking in 1826, according to Rennie, when a bridge of 100-ft span was constructed on the

---

[51] "History of Bridge Engineering," p. 23.

[52] Assoc. Prof. of Eng. Mechanics, Sheffield Scientific School, Yale Univ., New Haven, Conn.

[53] *Minutes of Proceedings*, Inst. C. E., Vol. V (1846), p. 33.

Ancholme with complete success. He reported also that the lattice bridge had recently been introduced on the Birmingham and Gloucester Railway and on the Dublin and Drogheda Railway and that it had been found economical and simple in construction. A number of European types of wooden bridges, with details, was described by Benjamin Green in the same year[54] in a paper entitled "Arched Timber Viaducts."

Isambard Kingdom Brunel designed many timber railway bridges in a great variety of types.[55] Brunel was particularly concerned with the prevention of decay and, as early as 1835, was in communication with Faraday as to the best method of testing the extent to which Kyanizing solution penetrated into wood. It is reported that Brunel made a careful study of all the different methods of preserving timber, and used the more successful of them on a very considerable scale.

Many of the European engineers of these early times were well-educated men of high technical skill. Carl Friedrich von Wiebeking (1762-1842), mentioned by Rennie, was Director-General of Roads and Bridges in Bavaria, and was the author of several treatises on hydraulics, mechanics, and structures. He worked out proportions for his laminated wood arches for spans as long as 600 ft. Bridges of this type were built in England and on the Continent in considerable numbers. The authors' Fig. 6 is of this type, but in most of the bridges the bent planks were thinner — 3 in. being a common thickness. As many as sixteen or twenty thicknesses of bent planks were bolted together to form the arch rib.

Another good source of information concerning European timber bridges is the set of publications on the "Theory, Practice, and Architecture of Bridges," edited and published by John Weale about 1843; it contains two volumes of fine plates. The early volumes of *L'Illustration* also contain pictures of wooden bridges in the days when railroads were still objects of curiosity.

It is true, of course, that because the use of timber was less advantageous in much of Western Europe, than it was in the United States, bridges of other materials have always predominated.

The practice of assembling trusses on land before erection must have been more common than the authors imply. David Stevenson, a Scottish civil engineer, made an extensive tour of the Eastern United States and Canada, about 1837, for the sole purpose of inspecting engineering works.[56] He reported seeing many Town truss bridges on the Philadelphia and Reading, and on other, railroads.

He also noticed the Long bridge in many parts of the country, the best specimens being on some of the railways in the neighborhood of Boston, Mass. His account states, furthermore, that:

> "The timbers of which Town's and Long's bridges are composed, are fitted together on the ground previous to their erection on the piers. They are again taken asunder, and each beam is put up separately in the place which it is to occupy, by means of a scaffolding or centering of timber."

[55] "Life of I. K. Brunel, Civil Engineer," by Brunel, Lond., 1870.
[56] "Sketch of the Civil Engineering of North America," Lond., 1838.

Richard S. Kirby,[57] M. Am. Soc. C. E. (by letter).—The authors of this paper have covered in a thorough and interesting fashion a field too long neglected. The writer was especially pleased with their emphasis on personalities of the period. In this connection he ventures to add a word concerning the McCalls Ferry Bridge over the Susquehanna River, the work of Theodore Burr, Connecticut-born engineer and contractor, of Harrisburg, Pa. This bridge was one of Burr's great achievements, but little is heard of it because of the fact that it was carried down by the ice in 1817 after only two years' service. The writer believes that it had the longest span of any wooden bridge ever attempted in America, and that only that of the Schaffhausen Bridge had exceeded it.

In a long letter written by him shortly after he finished this bridge, to his friend, Reuben Field, bridge builder of Waterford, N. Y., Burr rehearsed graphically his thrilling experiences in erecting the bridge during the winter of 1814-15. The arches were fabricated in halves and raised at first on bents of varying heights supported by floats ranged along and parallel to the shore nearly $\frac{1}{4}$ mile below the site. As the ice increased in thickness, Burr decided to use it instead of the floats. He finally slid the entire structure up stream on rollers. Man-power was abundant in those days, in that locality at least, for Burr commends the inhabitants for their willing help, which was perhaps gratuitous.[58]

Wells N. Thompson,[59] Assoc. M. Am. Soc. C. E. (by letter).—In the early stages of the development of wooden bridges, the crib or corbel type was one of the most interesting. Examples of this type of bridge are fast disappearing as they are replaced by more modern structures, but there are a few remaining. Fig. 32 shows a very interesting one in the Far East.

This old bridge is well known throughout Japan, and it is shown or mentioned in many native wood-block prints, poems, and songs. It is located in Central Japan, Yamanashi Province, and supplies its own name to the nearest town, "Saruhashi" or "Monkey Bridge." It is fifty miles west of Tokyo and spans a mountain stream at a point where it is approximately 80 ft wide between abutments. Age is evident in the entire structure, but repairs and replacements have been made as required so that it continues in good condition and in general use for the traffic in that district, which consists largely of pedestrians, jinrikishas, and ox-carts. The roadway is about 12 or 14 ft wide.

The Japanese excel in timber construction, and are very careful about protecting their structures against rot and decay. In this bridge, as in all other structures where framing is exposed to the weather, they have protected each member in the supporting cribs with an individual roof or watershed. Such care has preserved many of their very old and notable structures.

---

[57] Assoc. Prof., Eng. Drawing, Sheffield Scientific School, Yale Univ., New Haven, Conn.

[58] The letter appeared in *Niles Weekly Register* (Baltimore, Md.), November 18, 1815. It is copied in the Lancaster Historical Papers, Vol. XI, p. 133.

[59] Danbury, Conn.

The abutments are field stone masonry, built against the rock walls, and have probably been added recently, in rebuilding or reinforcing the old stonework, perhaps after damage by earthquake.

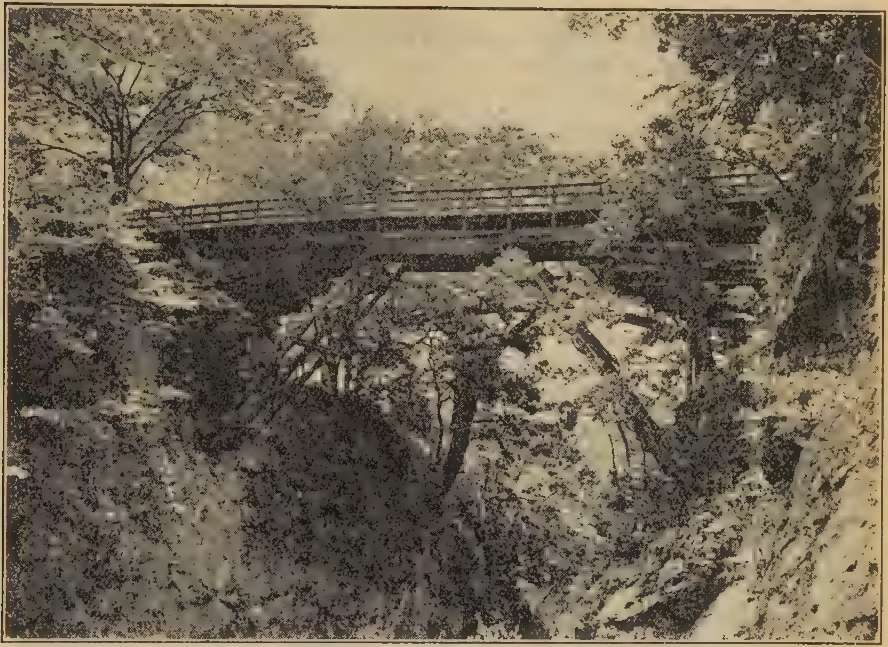

FIG. 32.—OLD CORBEL TYPE OF BRIDGE, YAMANASHI PROVINCE, JAPAN.

BENJAMIN WILDER GUPPY,[60] M. AM. SOC. C. E. (by letter).—In connection with Fig. 28 of the paper, the authors point out the important warning that the bridge builder cannot be too careful in designing the bolted and spliced joints of a timber bridge. A few examples should serve to emphasize this importance.

A draftsman who has had experience only in detailing metal structures has considerable difficulty when he first attempts to design a timber structure. In such a case the writer has told the man that if he designs a steel bridge while standing on his feet, he should stand on his head while designing a timber structure. In other words, the processes are reversed. In steel designing, the sections of the main members are determined first and then the details designed to transmit the stress properly. In straight timber work it is the design of the connection that generally determines the dimensions of the main members. In metal work the unit stresses to be considered are those of tension, compression, shear, and bearing. In timber the unit stresses to be accounted for are tension, compression, bearing on end grain, bearing across grain, shear parallel to fiber, and shear normal to fiber on planes parallel to and normal to direction of fiber.

---

[60] Engr. of Structures, B. & M. R. R., Boston, Mass.

The simplest case is a post in a trestle bent. In a steel structure the area of the post is determined by dividing the stress it is to carry by the allowable unit stress determined by some approved column formula. The dimensions of the timber post are determined by the stress in the post divided by the allowable stress in bearing across the grain on the cap or sill. A moment of reflection will show that it will be a very long slender post to require an allowable unit compressive stress as low as the unit bearing stress on side grain of timber.

The next step in advance is a king-post truss and to illustrate his statement the writer presents a design using timber entirely, use of iron being restricted merely to small bolts to hold the various pieces together (see Fig. 33). The king-post is in tension. To determine its proper dimensions both upper and lower connections must be considered. At the lower connection the size of the post is determined by the net area required in tension, plus the area required to transmit the stress by bearing across the grain. At the upper connection the area of the post is determined by the net area required to carry the tension, plus the area required to transmit the stress by bearing on the end grain. The larger of these areas governs. At the upper joint the strut must be framed both to give sufficient area for the vertical component in the strut at the unit stress for bearing on the end fiber and the horizontal component in the strut at the unit stress for bearing across the grain. The distance from the daps to the end of the king-post must be sufficient to prevent the timber from shearing beyond the daps. At the bottom of the strut the connection is reversed from that at the upper end as the horizontal component must be carried into the bottom chord through the end bearing and the vertical component through the side bearing. The bottom chord must extend far enough beyond the dap to give sufficient strength in the shear along the grain. The size of the bottom chord at the end joint is determined by the depth of dap necessary to transmit horizontal stress from the strut and

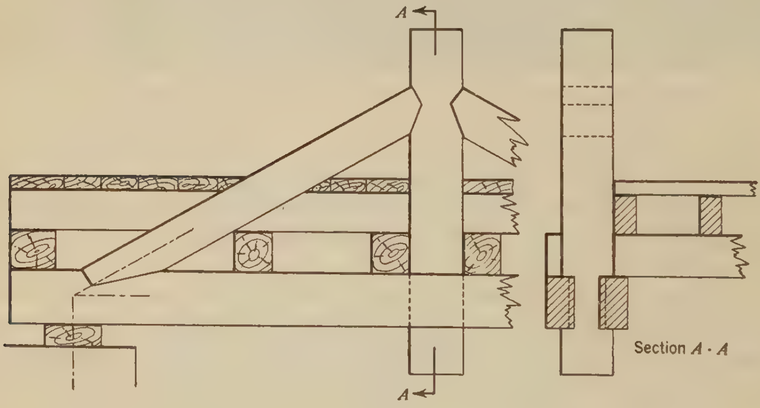

FIG. 33.

the depth of stick required below the dap to carry the tension in the bottom chord plus any bending that may be induced by eccentric connections or methods of loading.

When it is necessary to splice a tension member the design of the splice is necessary before sizes of timbers can be determined. This is not submitted as an example of good modern practice, but to illustrate principles of design in timber and to show what will have to be done if metal for details is not available. The use of metal angle blocks to distribute stress at connections will permit of detailing compression members in accordance with an approved column formula and the use of rods for tension members and joint bolts will greatly simplify detailing connections. Figs. 16 and 28 in the paper by Messrs. Fletcher and Snow show how efficiency of tension splices can be increased by a free use of metal.

IVAN E. HOUK,[61] M. AM. SOC. C. E. (by letter).—The authors have contributed an extremely interesting and valuable account of the history, design, construction, and life of wooden bridges.

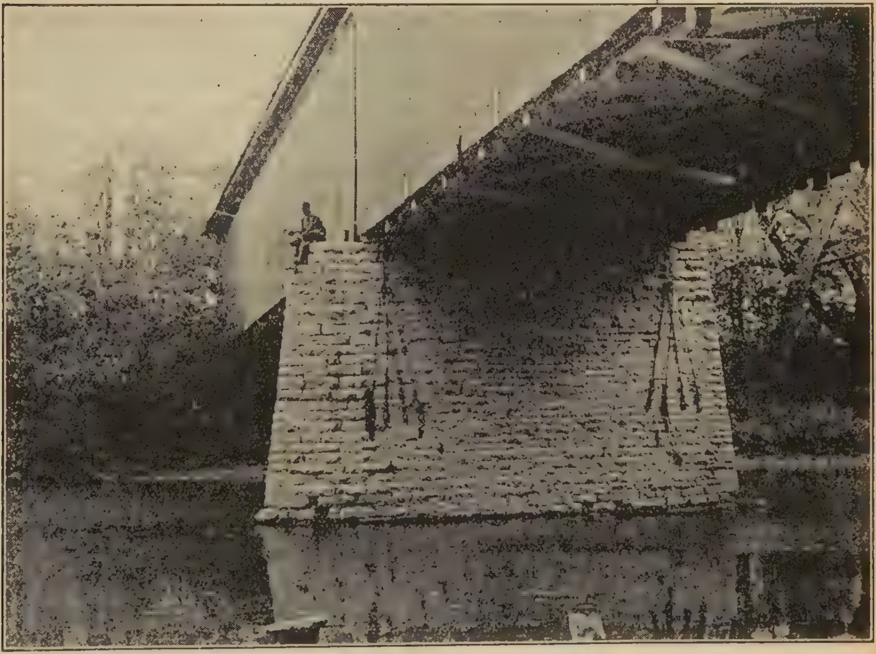

FIG. 34.—VIEW OF TIMBER TRUSS COVERED HIGHWAY BRIDGE OVER THE STILLWATER RIVER IN SOUTHWESTERN OHIO.

In connection with their discussion of retrieving weak and injured bridges, an account of the rather novel repairs shown in Fig. 34 may be worth while. This bridge is one of the old timber truss, covered highway bridges, still so common in the Eastern United States. It spans the Stillwater River, of

---

[61] Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

Southwestern Ohio, about two miles above the Englewood Dam. It withstood, safely, the disastrous flood of March, 1913, as well as all the previous floods that had occurred after it was built. When it was built, or whether it is still in existence, is not known. However, it must have been about fifty years old at the time the Englewood Dam was completed. The Englewood Dam is one of the five large flood-prevention dams built by The Miami Conservancy District about 1920 or 1921.

Prior to the completion of the flood-prevention works the bridge was located on the National Road and carried all through traffic along U. S. Highway 40 in that section of the State. Since that time through traffic has been routed over the top of the dam. However, the bridge was still in good condition at the time the dam was built, and it was desired to keep it in operation after the through traffic was diverted. Consequently, it was necessary to anchor it in place, to keep it from floating away during flood periods when the back-water above the dam might rise 30 or 40 ft above the roadway surface. In other words, the construction of the dam below made it necessary to hold the bridge down as well as up.

Iron rods, 1¼ in. in diameter, with an eye at the bottom and threads at the top, were placed vertically between the timbers of each truss, a rod being placed on each side of the pier and at each abutment. The upper end of the rod passes through the heavy timber which constitutes the upper chord and is held in place by a large iron washer and nut. The eye at the lower end is tied to the foundation by four steel cables, attached to iron bolts set in the masonry about 1 ft apart and about 12 ft below the lower chord.

The old, timber truss, covered bridges in the Miami Valley went through the destructive flood of March, 1913, as well as, if not better than, those of more modern design. Of course, this was because the masonry foundations had been either founded on rock or carried down to a sufficient depth below the bed of the stream, and had then been built to a height well above the maximum previous high-water level before placing the superstructure.

William H. Baker, Jr.,[62] Assoc. M. Am. Soc. C. E. (by letter).—The various developments in the use of wood for the construction of bridges, is illustrated clearly in this paper. It covers the development from the most simple type, through all the stages of design, to the present standard. The writer believes that the development of the wooden bridge has been a great influence on the history of the world, both in military conquest and social growth through the medium of communication. The wooden bridge is still used extensively in the United States, despite the great progress in the use of steel and reinforced concrete in the last twenty years.

The wooden bridge is still used much more extensively than bridges of steel and reinforced concrete in Los Angeles County, California. There are approximately six hundred bridges of wood construction in use at the present time. They consist principally of A-frames up to 42-ft span, together with pony Howe trusses for longer spans. The reason for this extensive local use of the wooden bridge is due to the inadequate finances available to construct a more permanent type of crossing over the many dry washes in the county—most of them dry, except during flood stages—and also because as yet flood-control channels have not been established in many instances. Some of these wooden bridges over dry washes are as long as 800 to 1 000 ft, and to have built them of steel or concrete would have increased the cost many times that of the wooden structures; and after the flood-control channel had been established definitely, the channel would perhaps be much narrower than the original bridge span.

---

[62] Cons. and Structural Engr., Long Beach, Calif.

Since about 1925 or 1926 it has been necessary to widen many existing highways in Los Angeles County. The early bridges had 20-ft roadways—inadequate for present traffic needs. Most of the bridges now constructed have a roadway width which will be sufficient to provide for present traffic demands and for future widening of the highway. It was necessary, therefore, that the County Road Department adopt a policy in which all future bridges would provide roadways of at least 30 ft. The wooden bridges, both the **A**-frame and the Howe truss type, were constructed using large Oregon pine floor-beam members. These floor-beams for a bridge without skew were 24 ft long for a 20-ft roadway, being made up of two 12 by 36-in. timbers bolted together. For skew bridges, the floor-beams were longer, as the angle of skew increased, making these beams from 24 ft to approximately 36 ft in length. It was very difficult to build wooden bridges for a 30-ft roadway utilizing wooden floor-beams, due to the length requirement of such a large wooden section. At the same time, the cross-sectional area required for the wooden floor-beams greatly reduced the head-room and opening for the waterway.

At the time that the Carnegie beam sections using flat flanges were introduced, the Bridge Department of Los Angeles County designed and developed a wooden truss bridge of the Howe type for 30-ft roadways, and for various angles of skew, utilizing the new Carnegie beam sections of 30, 36, and 42-in. depth for floor-beams replacing the old wooden type beams. A very simple method of constructing a proper connection for the hanger rods and extension brackets for the pony truss braces was designed and developed. This use of the Carnegie beam section as floor-beams, which has now (1933) been standard for five years, permitted the design and construction of wooden bridges of 30-ft roadway and a much greater angle of skew than was possible with wooden floor-beams. At a later date, about two years after steel floor-beams were utilized, the lower tension chord member was designed, with steel channels to replace the old, built-up, wooden type lower chord.

The principal difficulty experienced with bridges of the wooden type was the dry rot that developed in the end-posts and flooring. Several types of construction have been tried over a period of years to eliminate this, including the use of 2 by 6-in. timbers of Oregon creosoted pine, laid on edge and the utilization of diagonal planking overlaid with transverse planking at right angles and surfaced with asphalt or macadam.

It is impossible to state or give true results at the moment as to which type or method of wooden floor construction is superior. Later, due to the difficulty in maintaining the wooden type of floor construction, a reinforced concrete floor-slab system placed on timber stringers was tried as an experiment. Several bridges utilizing such construction have been in place for about four years, and to the present time (1933), are in good condition. However, it is problematical whether this method will prove to be entirely successful and will replace the old method of wooden floor construction. The bridges that the writer last described are not strictly wooden, but are a combination of wood, steel, and concrete.

The use of the wooden bridge in Los Angeles County will probably continue for some years to come, until flood-control channels are definitely established and until new means of financing permanent structures of concrete and steel are advanced. The use of the wooden bridge is very costly, due to the heavy maintenance charges involved. However, they will have to serve until something more economical from the standpoint of first cost is substituted. This paper is of unusual interest and is a great contribution to civil engineering history.

Oren Reed,[63] Assoc. M. Am. Soc. C. E. (by letter).—The authors are to be commended for their excellent history of the development of different types of wooden bridges, a class of engineering structure that is fast disappearing in Central and Eastern United States. Since the structures described were located in the Eastern States, the writer wishes to refer to a few wooden bridges of Indiana to show the wide range in the use of such bridges. Most of these old structures, which are still in use, are on little back roads, off the main highways, and in out-of-the-way places; but a few are on major routes, such as the multiple-span bridge on the present U. S. Route No. 50 over the East Fork of White River, near Medora, and the two-span bridge on State Road No. 52, at the edge of Rushville, over Flat Rock River.

Nearly all the early covered bridges in Indiana were of the Burr truss type. The Howe truss soon superseded the Burr truss, to a large extent, in the East, but was not commonly used in Indiana, and probably not at all before 1865. The National Road, the Michigan Road, and the Vincennes-New Albany Pike were the early important roads and most probably the ones on which the first permanent bridges were built. For most of their lengths, these have remained important roads, and only a few of the original bridges remain.

Mr. J. J. Daniels, of Rockville, and the Kennedy family, of Rushville, are largely responsible for the great number of excellent timber bridges in the State, many of which are still in use. Mr. Daniels built about fifty bridges, mostly in Parke and Vermillion Counties. He built a bridge over Sugar Creek, in Parke County, in 1861, which is still in use. This structure has a clear span of 200 ft and is the longest single-span covered bridge of record in Indiana. The Kennedy family built about sixty covered bridges in all, the first being at Dunlapsville, in Union County, in 1870, and the last near Fountain City, in 1918. Many of these bridges are still in use in Southeastern Indiana. The Burr truss bridge, at Rushville, built by the Kennedys in 1883, has two 125-ft spans with a 16-ft clear roadway, and is unusual in that it has an arcaded sidewalk on each side.

---

[63] Constr. Engr., Emergency Conservation Work, Camp 2, Lincoln City, Ind.

Two of the oldest timber trusses, still in service, are the Ramp and Raccoon Creek Bridges formerly on State Road No. 43, near Greencastle, which were built in 1837 and 1838. These bridges were constructed of local material, except for a few hand-made iron bolts and brace-pins. Both have two 11-ft roadways carried by three trusses, one of which separates the two roadways. The Ramp Creek Bridge has a clear span of 91.5 ft and the Raccoon Creek Bridge, one of 120 ft.

The Ramp Creek Bridge was removed in 1932 and re-erected over Salt Creek, at the north entrance to Brown County State Park, by the Indiana State Highway Commission. The arch ring, top chords, rafters, and roof framing are of yellow poplar; the posts, lower chords, and floor are of oak; while the floor-beams, joists, and sub-flooring are of walnut. Members that had decayed to any extent, were replaced by new timber. Oak was substituted for the damaged walnut. In all, 10 to 15% of the members were replaced. The abutments, which were carried to rock, are of concrete, faced with sandstone masonry. This timber bridge will have ample strength to carry the park traffic and should stand for many years as a monument to the early bridge engineers and their ingenuity in the use of local materials. Raccoon Creek Bridge is also to be replaced by a modern bridge to care for the heavy through traffic on State Road No. 43. Another timber bridge, maintained by the Indiana Department of Conservation, spans Sugar Creek, in Turkey Run State Park, at the Narrows Crossing. It has a span of about 100 ft.

R. P. DAVIS[64] and L. L. JEMISON,[65] MEMBERS, AM. SOC. C. E. (by letter).—The authors of this paper merit the thanks of the Engineering Profession for their effort to record the history—from an engineering standpoint—of the fast-disappearing wooden bridge. Much of a general nature has been written on this subject in the last few years, most of which is, however, not from the engineer's point of view.

During the latter part of the Eighteenth Century, in building highways to connect the Ohio country with the Eastern seaboard, the stone arch was widely used, as exemplified by those on the National Highway between Hagerstown, Md., and Wheeling, W. Va. A little later the wooden bridge became the more popular, and from the beginning of the Nineteenth Century until after the Civil War wooden bridges were very common west of the Allegheny Mountains, the Burr type being almost exclusively used, without arches for the shorter spans. Nearly all these bridges were protected with roofs and side covering, with an open space at the top to permit proper ventilation.

FIG. 35.—BRIDGE OVER CHEAT RIVER, NORTHWESTERN TURNPIKE, PRESTON COUNTY, WEST VIRGINIA

Of particular historical value is the two-span combination arch and truss bridge over the Cheat River above Rowlesburg, W. Va. (see Fig. 35). This structure is on the old Northwestern Turnpike (later known as Federal Route 50), a highway built in 1832 under Col. Claudius Crozet, who had been an officer of artillery under Bonaparte in the Russian campaigns.

Completed in 1834 it has given excellent service for a period of more than 98 years. The material is white pine with all timbers hewn by hand; all bolts are of wrought iron with large heads. The bridge was built at a cost of $18 000, or $2.40 per sq ft of roadway, on the basis of a total length of 339 ft, and a clear roadway width of 22 ft. The arch ribs are composed of three 6 by 11½-in. timbers, placed vertically one above the other, an arrangement not as common as placing them side by side horizontally. However, by this arrangement (see Fig. 35), less notching is required, and the full section of the arch may be secured. The stringers, 6 by 8 in. in section and spaced 3 ft 9 in. apart, are larger than those customarily found in highway bridges of the early days. The 7 by 10-in. floor-beams are hung from the lower chords by two 1-in. bolts. Why the more common and simpler method of placing these beams above the chords was not used, is not apparent. However, this method of support gave complete satisfaction, because the original bolts are still (1933) in an excellent state of preservation.

It is interesting to note that the tension web members of the trusses are not placed vertically, as is more usual, but inclined in a direction approximately normal to the arch ribs. Loads from the floor-beams first come to the trusses and are transferred to the arch rib by notching the so-called verticals and by placing wedges between the three rows of timbers forming the arch rib. It will be observed that these trusses have only a single system of diagonals. As these diagonals are framed so that they take only compression, the question naturally arises as to why a double system was not used. The sticks composing the arch rib and the lower chords are three panels in length. The type of splice used for the lower chord would be considered now a very poor one for a tension connection.

During recent years a double floor has been used on this bridge, together with longitudinal runways. These were necessary on account of the wide spacing of the stringers. When heavy truck loading was introduced, considerable weakness developed in the floor-beams in resisting horizontal shear near the ends. This weakening was due to the notching of the floor-beams at their ends and also to the cutting of holes to permit framing the diagonals of the lower lateral system.

Most of the timbers composing the trusses and the arches are in an excellent state of preservation, except the arch ribs near the springing points where, due to failure to carry the siding down in the early years, considerable rotting developed. The bridge has also suffered under the action of some severe storms, as a consequence of which the trusses and arches are badly bowed out of line. The substructure is composed of stone masonry laid with close joints, without mortar. It is in good condition.

The bridge illustrated in Fig. 36 was on the famous James River and Kanawha Turnpike which was opened to traffic in 1800. The bridge was built in 1872 across the Greenbrier River, at Caldwell, W. Va. It had two spans, the arches being 228 ft long. Like the Cheat River Bridge it had a double roadway, the outside trusses being 25 ft, center to center. It was the second bridge to be built at the same location; the first one, constructed in 1807, was burned during the Civil War. The second bridge was built at a cost of $12 500, or $1.40 per sq ft of roadway, the superstructure resting on the original pier and abutments. When this masonry was torn down in 1932, the piers and abutments were found to be composed of stone masonry shells backed with small stones.

FIG. 36.—BRIDGE OVER GREENBRIER RIVER, AT CALDWELL, W. VA.

The floor system has 3 by 8-in. stringers spaced on 2-ft centers, resting on 7 by 12-in. floor-beams, which, in turn, rest on the lower chords of the trusses. As the trusses and arches resemble very closely those to be described hereafter for the Philippi Bridge, neither these details nor the roof covering is shown on the drawing.

The bridge illustrated in Fig. 37 is over the Tygarts River, at Philippi, W. Va. Built in 1852, it is said to have been the scene of the first land

FIG. 37.—BRIDGE OVER TYGARTS RIVER, AT PHILIPPI, W. VA.

battle of the Civil War. It has two spans, the arches being 138⅔ ft long. The bridge has a peculiar stringer system composed of diagonal 3 by 8-in., 3 by 10-in., and 3 by 12-in. beams, notched half and half into the floor-beams and into 6 by 8-in. timbers placed on, and running parallel with, the lower chords. This type of connection has proved very weak under concentrated loading and has given considerable trouble by horizontal shearing at the ends of the stringers. No lower lateral system was used on this structure, probably for the reason that the stringers, being framed into the floor-beams and pinned as well, were expected to serve as bracing. The excellent type of fish-plate joint used for lower chord splicing should be noted.

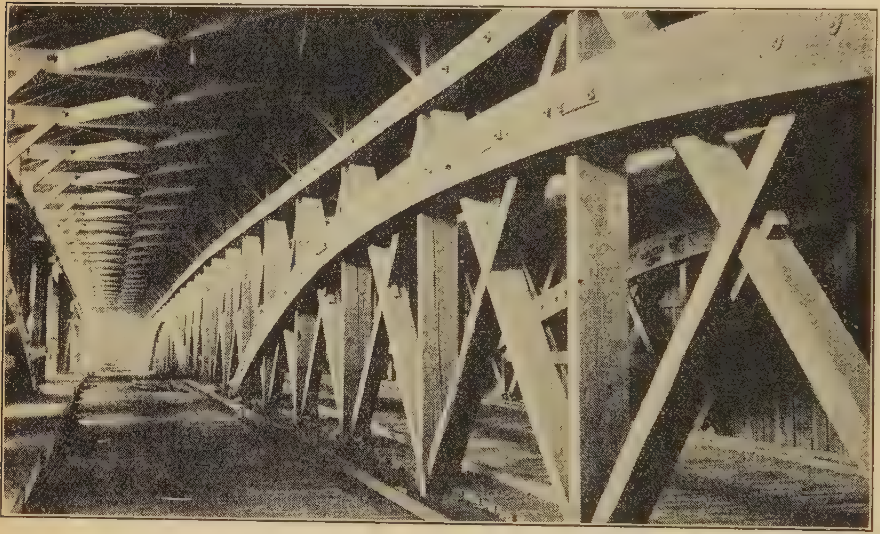

FIG. 38.—INTERIOR VIEW OF PHILIPPI BRIDGE

The bridge was built by Lemuel Chenoweth, of Beverly, Va. (now W. Va.). Mr. Chenoweth was a bridge architect by profession, and it is said that his designs were original with him, and every principle was worked out with mathematical accuracy. He knew beforehand the shape and size of every piece of timber used in the framework of his bridges. The contract for this bridge was let at Richmond, Va. Bidders were present in large numbers with all kinds of models and plans. As far as appearances went, it is said that some of the New England Yankees had models of perfect form and beauty, painted and enameled in the highest art. Mr. Chenoweth's plain wooden model attracted little attention until he placed it on two chairs, one end resting on each, and then stood on his little bridge, and called on the other architects to put theirs to the test by doing the same. This feat got him the job of building the bridge.

Considerable decay of the arches has occurred near the springing lines, but all timbers that have been properly protected are in good condition. After eighty years of continuous use this structure still lines up almost perfectly.

The details of the trusses and arches are quite similar to those of the Waterford Bridge (Fig. 15) described by the authors. Fig. 38 gives a view of the interior of the Philippi Bridge.

The only metal in any of the bridges described was in the form of bolts, which were freely used to hold the various members, and their segments together; but in no case, except the floor-beam connections and the lower chord splices of the Cheat River Bridge, do these bolts take any primary stress. The transfer of load from one element to another was accomplished by direct bearing or by notching. Wedges were used quite freely to take care of shrinkage conditions and wooden pins were utilized in the bracing systems.

PETER T. LANDSEM,[66] ASSOC. M. AM. SOC. C. E. (by letter).—The authors deserve much credit for their thorough investigation of the development of wood bridges in the United States. However, the paper gives the impression of being an epitaph on wood bridges, which is not deserved. Certain developments in the more efficient use of lumber both in Europe and in the United States indicate that the world is probably on the threshold of a renaissance in wooden bridge construction.

In general, information on the period from the collapse of the Roman Empire up to 1500 A. D., seems to be lacking in the authors' treatise. Improvements were small, which is astonishing in view of the highly developed church architecture, both Romanesque and Gothic. Most bridges were simple trestles. An outstanding example was the one built over the Rhine, at Basel, Switzerland, in 1225, and first replaced in 1903.

It might be of interest to state that Palladio did not consider himself the inventor of the truss. He refers to a truss with parallel chords, verticals, and single compression diagonals found in use in Germany by Picheroni de Mirandola.

The authors state that "covered or roofed-in bridges were distinctly not a feature in European practice," yet there is evidence that covered bridges were known in Germany and Switzerland long before the famous Ulrich Grubenmann and Josef Ritter became active in bridge construction early in the Eighteenth Century. One of the oldest of such bridges from the Middle Ages, still in existence, is the picturesque "Kapellbrücke" over the Reuss, in Luzerne, Switzerland, built in 1333. Similar bridges were built in the Sixteenth Century with spans up to 22 m. In 1658, a covered bridge with a span of 32 m was built over the Rhine, at Stein-Säckingen, Germany. Dr.-Ing. K. Schaechterle,[67] has called attention to a number of covered bridges, and advice concerning the construction of covered bridges has been published by L. Chr. Sturm;[68] J. Leupold;[69] Johan Wilhelm;[70]; and Johann Vogel.[71]

Developments in Europe in the Nineteenth Century.—The authors of this treatise do not trace the development of wooden bridges in Europe after the middle of the Eighteenth Century, and do not cite any examples of such bridges built in the latter part of the Nineteenth Century in the United States.

A brief summary of the development in Europe may be of interest. About 1800, Funk, in Germany, applied to bridges a wooden arch that had been used for roofs by the French architect, de l'Orme, in the latter part of the Sixteenth Century. The arches were made of boards on edge, cut to shape, and nailed and doweled together. This system was not satisfactory, however, because in shaping the boards the grain of the wood was cut too much and because water entered so easily into the vertical joints.

In 1809, Wiebeking, another German, used for bridges the system generally attributed to the French Colonel Emy, although not in use by him until 1819. The boards were laid flat and nailed and bolted together. This type of arch, however, was too flexible even when braced. Load tests on both de l'Orme's and Emy's systems were carried out by the French military engineer, P. Ardant.[72]

Although the railroads increased the demand for bridges early in the Nineteenth Century, no significant improvements originated in Europe. It was left to the United States to develop the combined arch truss into the framed trusses of Long, Howe, and Pratt. From the middle of the century the art of wooden bridge building went into a decline. This must be attributed mainly to lack of knowledge concerning the properties of wood and concerning reliable framing methods. Engineers of that day lost interest in wood construction. In fact, the only new idea that has come to the writer's attention are the gallow bridges in Trondhjem, Norway.

Modern Developments in Wood Construction.—New interest in wood construction was created about 1900 by carpenter-contractors who, having acquired some technical knowledge, put up structures that caught the interest of engineers. The engineers have carried the developments further. Therefore, in Germany to-day, they speak about "Ingenieur-Holzbau," or engineering wood-construction.

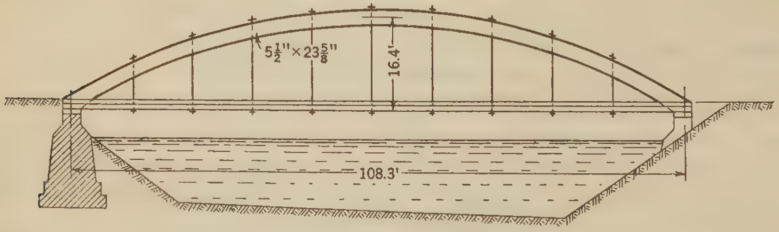

FIG. 39.—SECTION OF FOOTBRIDGE OVER THE WIESE RIVER AT BASEL, SWITZERLAND

---

[72] "Theoretischpraktische Abhandlung über Anordnung und Konstruktion der Sprengwerke von grosser Spannweite," von A. v. Kaven, 1847.

Stephan made Emy's arch stiffer by building it like a truss of curved laminated chords, doweled together, and braced by cross-diagonals. This system, however, was used only for roof trusses. The railway station in Copenhagen, Denmark, is a good example.

Otto Hetzer introduced his laminated glued-wood arch in 1907. It consists of boards laid flat, curved, and glued together, the glue being water-resistant and having at least the same strength as the wood. An early example is the foot-bridge over the Wiese, at Basel, Switzerland (see Fig. 39), which was built in 1910. The roadway is suspended from the two-hinged arches, 33 m (108.3 ft) in span. It was computed for a load of 350 kg per sq m (72 lb per sq ft) and cost 6 200 francs, which was only one-half the nearest bid in steel. Th. Gesteschi[73] and H. Lewe[74] mention other arch bridges.

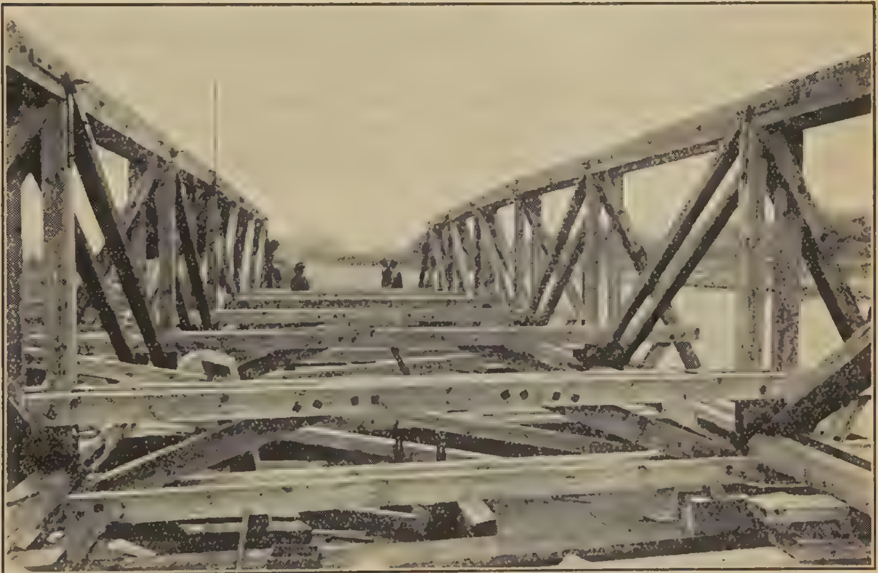

FIG. 40.—VIEW OF CONSTRUCTION BRIDGE OVER THE SPREE, BERLIN, GERMANY; CLOSE-UP OF ONE SPAN

During the World War the simple truss was improved and the trussed frame was introduced with the use of new and more efficient joining devices. Modern European literature refers to many wood bridges. A covered bridge over the Neckar, at Thalhausen, Germany, was built in 1924. It has three spans, 62.3 ft long and two spans, 32.8 ft long. Others are: A suspension bridge at Sulitjelma, Norway, 266 ft long (maximum span, 177 ft); a pipe-line suspension bridge in Finland, with four spans of 167 ft each and a total length of 984 ft; a footbridge at Neumünster Railway Station, in Germany (maximum single spans, 131 ft, and total length, 541 ft); and a military road bridge in Norway (span, 85 ft). Well known foreign sources of information are: Th. Gesteschi;[75] C. Kersten;[75] and A. Laskus.[76]

Introduction of Modern Wood Construction Methods in the United States.—It has been recognized that the chief drawback in the use of wood to-day in bridge construction has been the inefficient joint. In bolted connections the safe loads determined by the various handbook methods differed widely. This situation, fortunately, has been relieved by an extensive series of tests[77] carried on for years at the Forest Products Laboratory, U. S. Department of Agriculture. The Engineering Staff of the National Committee on Wood Utilization, U. S. Department of Commerce, in co-operation with the Forest Products Laboratory, U. S. Department of Agriculture, has been investigating still better joining devices which, as tests show, may increase the load capacity from two to six times (and even more) than that of an ordinary bolted joint.

Fig. 40 shows a bridge in which modern connectors are used in the joints. These joining devices or connectors, comprising various types of rings, plates, and disks embedded in the sides of timbers (see Fig. 40), are used for transmitting the load from one member to the other. Fig. 41[78] is the view of a joint composed of modern connectors developed in Germany.

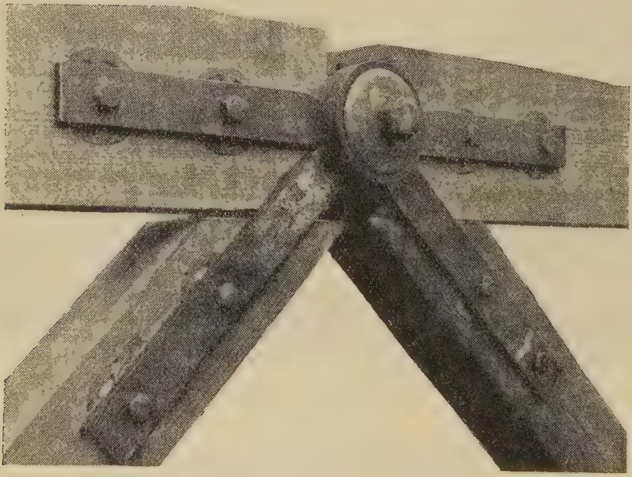

FIG. 41.—VIEW OF JOINT COMPOSED OF MODERN CONNECTORS

In concluding, the writer would like to call attention to the fact that the State of Oregon is building timber highway bridges, using the money thus saved for better road surfaces.

[77] *Bulletin No. 332*, "The Bearing Strength of Wood Under Bolts," by George W. Trayer, 1932.

[78] "Modern Connectors for Timber Construction," by Nelson S. Perkins, Peter T. Landsem, and George W. Trayer, *Bulletin No. 24*, National Committee on Wood Utilization, U. S. Dept. of Commerce.

J. K. Finch,[79] M Am. Soc. C. E. (by letter).—One or two books on American timber bridges have appeared in recent years, but this paper is the first to record and discuss some of the interesting technical details involved in early timber bridge construction. While the men who built these bridges were simply self-taught Yankee carpenters, their abilities were of the first order and from their labors the truss bridge, a typically American contribution to engineering progress, was evolved.

The writer has no details to add to the record of these master builders as given by Messrs. Fletcher and Snow. There are, however, a few notes that might be of interest on the place this timber-bridge era occupies in the great epic of engineering achievement.

The authors mentioned the lack of bridges in ancient Greece. The same observation would hold for Egypt and Mesopotamia. This was not due to any lack of ability on the part of the Greek architecton, or master builder. (The name, architect, is derived from this title but it is preferable to translate architecton, and the later Roman architectus, as master builder, for, until the introduction of a new technique with the advent of gun-powder in the early Renaissance, the present professions of civil and military engineering and architecture were all included in this single name). Topography was a most important element in shaping the course of engineering development. Thus, the Nile and the Tigris-Euphrates furnished the transportation routes for these two most ancient civilizations. Roads, and hence bridges, were not required. Again, Greece has been described as a huge, bony hand stretching out into the Eastern Mediterranean and Aegean Seas. The construction even of trails across her rock-ribbed peninsulas was difficult. A unified Greek nation was topographically impossible. Roads, as an important element of communication, were not to be thought of. The Greek City States turned to the sea. The first naval battle of the world was fought by the Greek and Persian fleets at Salamis, and the Greeks naturally became the first of ancient harbor builders.

The topography of the Roman peninsula, on the other hand, made it physically possible to consolidate this great area and its many tribes into a single nation from the Alps to the heel of Calabria. This opportunity was taken advantage of by the strongest tribe, the Latin race, and the construction of roads, and necessarily of bridges, became an inevitable, a basic element, to this consolidation. The Alps shut off France from Italy, but France also was consolidated by another great Roman road and bridge-building development, while communication between the seaports of Southern France and Northern Italy furnished the connecting link.

Centuries later, in the United States, economic pressure from the seaboard States, the struggle of each State to secure trade advantages from the expansion westward which followed the Revolution, combined with the topographic problems involved, made the American canal and railroad era, and its accompanying bridge development, inevitable. It was not only Yankee ingenuity, or the force and initiative of a pioneer people, that made the United States the greatest nation of bridge builders the world has ever known. Topography and economic pressure have forced the people of this country to be ingenious and progressive in this particular field.

---

[79] Renwick Prof. of Civ. Eng., Columbia Univ., New York, N. Y.

It is also interesting to reflect on some other factors and forces that led American engineers to develop the truss bridge.

Palladio's famous timber truss of about 1540, mentioned by the authors, is well known. The first metal truss, however, had been built centuries earlier, under the Roman Engineer-Emperor Hadrian, to support the portico of the Pantheon at Rome. Undoubtedly, the truss form was used by the Greeks and, later, by the Romans in many roof constructions. Timber, however, was recognized as temporary, and the fire hazard was also considered. Hadrian's truss, for example, was of bronze and was clearly a pioneer attempt at fireproof building construction. (It was removed and melted for making cannon under Pope Urban VIII in 1625, but early drawings show its form and details.) Timber bridges, although undoubtedly used, were replaced by fireproof, durable stone arches whenever economic conditions warranted permanent construction. Hadrian's effort to build framing in metal was interesting, but of no economic importance because metal was too costly. In fact, the truss, an invention in framing, did not emerge, was not discovered or invented, until a civilization arose which was based almost entirely on timber construction. Colonial America was such a civilization.

David Stevenson, the British engineer, writing[80] in 1838 defended the use of timber and temporary constructions by American engineers, a practice which had been criticized by European workers. He pointed out that labor was scarce in the States, funds were not available for costly stone constructions, and the unknown future requirements as to loads and sizes of structures made temporary construction advisable. Construction in timber, therefore, represented not only economical design, but also good engineering and business foresight.

How much such pioneers in this field as Palmer, Burr, and Wernwag were indebted to earlier European bridge builders for their basic ideas, will probably never be definitely known. "Copying" may not have occurred at all. Indeed, books were scarce, and American Colonial carpenters would not be expected to have or see them. This point, however, is unimportant. These men and their associates, as well as earlier workers, apparently had no very clear conceptions of truss action, or at least did not have full confidence in such framing. Their bridges were "statically indeterminate" combinations of arches with "stiffening" trusses. Nevertheless, the germ of the truss principle existed in their work, and ultimately the truss emerged from their composite structures as a form capable in itself of carrying the full load. Town, Long, and, finally, Howe (1840) saw this element in the work of Palmer, Burr, and Wernwag, and the truss was thus brought forward as a distinct and separate structural form.

During this period of truss evolution, British engineers stuck stubbornly to their metal arches, girders, and "tubular" bridges. American engineers, following Haupt and Whipple, began to analyze the stresses in trusses. There was an era of patented trusses in which Pratt, Warren, Bollman, and others contributed to the evolution of economic truss forms. The timber and wrought iron was translated into the cast and wrought-iron construction of the Sixties, and then into the all-steel truss of the Seventies and Eighties. Finally, the engineers of the present day have contributed the great alloy steel spans of the modern highway era.

---

[80] "Sketch of the Civil Engineering of North America," pub. by John Weale, Lond., 1838.

The work of the early American timber bridge builders, therefore, represents only one step in the history of a great development. Their contribution to engineering progress, however, entitles these pioneer American bridge engineers to a prominent place in the annals of a great profession.

A. A. EREMIN,[81] ASSOC. M. AM. SOC. C. E. (by letter).—A number of ancient wooden bridges have been described (in Russian) by Mr. L. Nikolai,[82] a reference to which should be made in connection with this paper. For example, he shows the Trajan Bridge over the Danube River at the Iron Gates built by Apollodorus about 109 A. D. This is the bridge to which reference was made by the authors. The clear span was 118 ft, and the stone piers were carried 20 ft below water level. The Trajan Bridge is known as the first wooden arch bridge.

A freedom of the creative imagination at the beginning of the Nineteenth Century is well illustrated by Mr. Burr's bridge,[31] at Schenectady, N. Y., built in 1808. The curved chords were formed of eight 4 by 14-in. planks, spiked, and bolted together. After twenty years of service the bridge was reinforced with additional intermediate piers built in the middle of each span, and, in 1873, the structure was replaced by a metal bridge.

Among the notable wooden bridges built in Russia, Mr. Nikolai has described the "rainbow" arch bridge with suspended deck and a clear opening of 257 ft, spanning the Wepr River at Ivan Gorod Fortress.

In crossing navigable rivers the Russian builders used a removable bridge with draw-spans that were easily opened. The bridge was removed in winter when the river was covered with ice, and in spring, to permit a heavy mass of floating ice to pass at high water.

A primitive type of removable bridge is the floating type of structure. The deck of a floating bridge built in Riga (Fig. 42), was formed of planks 3 in. thick on 6 by 6-in. joists spaced at 3-ft centers and placed on 6 by 12-in. beams spaced at $3\frac{1}{2}$-ft centers. The beams were bolted to the 13 by 13-in. floating longitudinal beams. The average life of this type of floating bridge was about ten years. Later, the floating bridges were replaced with pontoon bridges, the spans being carried on wooden or metal barges.

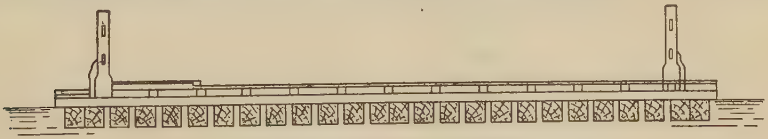

FIG. 42.—FLOATING BRIDGE

---

[81] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.
[82] "Bridges," by L. Nikolai, Russian Edition, 1901.

AKSEL ANDERSEN,[83] M. AM. SOC. C. E. (by letter).—The following data on wooden railroad bridges built in Norway between 1860 and 1875 is of interest in connection with this instructive paper on the development of wooden bridges. During that period the Norwegian Government constructed several important railway lines, including the northern half of the railroad between Oslo and Trondhjem, and several lines in the southeastern part of the country.

A great variety of conditions were encountered, involving the bridging of numerous rivers and deep valleys in mountainous country, with poor transportation facilities. Skilled carpenters and excellent pine timber were available, however, at low cost, and the selection of wood as the principal building material was natural. Stone or iron bridges would have been much more expensive and would have required a longer construction period.

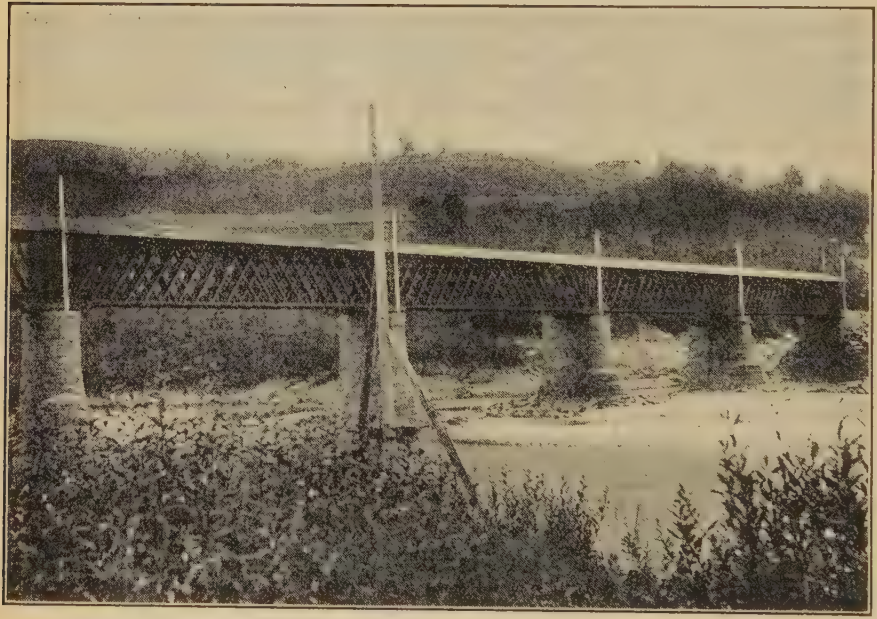

FIG. 43.—VIEW OF GULFOSS BRIDGE

In the lowlands the pile trestle was a common type, with spans as great as 40 ft. Compound keyed stringers with queen or king-braces were used for the longer spans. Practically all structures of this type were built of round, or half-round timber, and the joints were held together with iron screw-bolts.

For river crossings and high viaducts, with spans up to 100 ft, Pratt trusses and Howe trusses, with one and, in a few cases, with two systems of web members were used. Fig. 43 shows a bridge (Gulfoss Bridge), with four continuous-truss spans of 100 ft and several shorter spans. The continuous trusses are of the original Howe type with two web systems, very similar to the trusses of the bridge over the Connecticut River, at Springfield, Mass., shown in Fig. 24. The only apparent difference is the absence of braces against the piers below the lower chord. The same system of continuous 100-ft spans, with two systems of web members, was used in two other railroad bridges, and one of them (the bridge over the Gula River, at Stören), is still in use (1933) after nearly seventy years of service. (In this connection note the statement by Messrs. Fletcher and Snow under "The Howe Truss," that "it is not known to the writers that there has been another bridge built of the Howe type with webs of two systems"). The Gulfoss Bridge and several other through railroad bridges were protected by roofs, extending about 6 ft outside the trusses, with no side coverings.

---

[83] With Ash-Howard-Needles & Tammen, New York, N. Y.

Deck spans with simple Howe trusses, or Pratt trusses, supported by timber piers on masonry bases, were used in a number of high viaducts. The Dröja Viaduct, shown in Fig. 44, had one 100-ft, and seven 45-ft, truss spans of the Pratt type. The upper chords and the post were made of wood, but the diagonals and the lower chords were of iron. The diagonals of the 100-ft span consisted of two rods varying from 2⅛ in. in diameter at the ends to 1 in. at the center. The diameter of the threaded ends of the rods was ¼ in. larger than that of the rod; the threaded sections (6 in. long) were attached to the rods by welding. The welds were, obviously, points of weakness.

The wind system consisted of timber crosses in the plane of the upper chords with iron tie-rods at the panel points, and timber cross-frames at each panel point with iron tie-rods at the lower chords. The writer recalls an incident, in about 1916 or 1917, that proved the efficiency of this type of wind stiffening. One of the iron diagonals in a Pratt truss of a high timber viaduct failed, and several trains had probably passed over the viaduct before the break was detected. The only reason why the structure did not collapse was that the load was carried by the other truss and the wind system. A few typical details are shown in Fig. 44.

The Dröja Viaduct and other deck bridges and viaducts of the same type, were protected by a wooden roofing, extending about 3 ft beyond the outside faces of the upper chords. The trough-shaped part between the rails was made of longitudinal boards, covered with iron plates in order to reduce the fire hazard. The roofing outside the rails consisted of two layers of 1-in. by 6-in., transverse boards sloping slightly outward. The boards in each layer were placed with a spacing of 2 in., thus overlapping the boards of the other layer by 2 in. The contact surfaces between the two layers were provided with grooves for drainage (see Fig. 44). A similar system was used for wooden floors of highway bridges. The wearing surface consisted of longitudinal planks, and the loads were carried to the stringers by two layers of overlapping and grooved planks.

Simple Howe trusses, with iron rods as verticals, were used in a number of railroad bridges and viaducts. In some of them, the angle blocks were made of wood (usually oak), but more frequently they were of cast iron.

Practically all wooden bridges designed and built by the Norwegian Government Railways in the aforementioned period have been replaced, in recent years, by stone or steel bridges, or have been eliminated by re-location

of the lines. Record drawings, based on field measurements, and a number of photographs of the more important bridges have been collected by the Railway Museum at Hamar.

The writer wishes to acknowledge his indebtedness to Hans Tönnessen, Chief Engineer of Bridges of the Norwegian Government Railroads, who furnished drawings, photographs, and other data for this discussion.

William G. Atwood,[84] M. Am. Soc. C. E. (by letter.)—This paper has great historical interest and contains many lessons for engineers in active practice to-day. The interest created by the development of new or improved materials and the very intelligent advertising and salesmanship of their producers have caused the virtues of some of the older materials to be disregarded.

It is the duty of the engineer to build the cheapest structure that he can, which will be fully adequate for its purpose. If he studies this paper carefully he is likely to question whether many times a full timber or a composite structure, when taking into account interest on investment, maintenance, probable obsolescence, and salvage value, is not really a better and more economical structure than one built entirely with the newer materials.

Most of the structures described by the authors were built of timber because it was the only material physically available. This is still true to-day in a few isolated cases. The writer had a part in the construction of the Alaska Central Railway (later, the U. S. Government Railway), on which, in a distance of 4 miles, there was a total of more than 1 mile of timber bridges, part trestle and part Howe truss. This work was done in 1906 and 1907 when no transportation except pack and wagon train was available and no other material could have been used. Examples of this kind are rare in the present day.

Under many conditions timber trestles or spans will be found more economical than concrete or steel if all factors of cost are taken into consideration, especially that of obsolescence or the possibility of future reconstruction or widening. As an example of this there may be mentioned a number of short-span, through, concrete girder highway bridges on one of the most important north and south through highways. These bridges were built a number of years ago and roadway widening became necessary. The old bridges had to be removed and were replaced by others of the same type. If, originally, they had been treated-timber pile bridges, their first cost would have been less, they could have been widened at a small fraction of the cost of the work actually done, and the treated-timber bridges would have lasted as long as bridges were required in these locations.

This paper not only shows the great ability of the preceding generations of engineers in using the structural materials available to produce bridges that were not only adequate for the loadings of their time, but capable of safely carrying much greater loads, but it also shows the inherent value of the material itself. Timber bridges carrying loads several times those for which they were designed for periods of 50 to 100 years cannot by any stretch of the imagination be called temporary structures.

---

[84] Cons. Engr., New York, N. Y.

When giving credit to their professional predecessors engineers should remember that they did not have the information that is available at the present day even regarding such an old structural material as timber; nor was treated timber available in any quantity until the last fifty years. As a result of the work of the U. S. Forest Products Laboratory, the Department of Commerce, and the various associations of timber producers and timber treaters, together with the engineering societies, there is available for the present-day designer information that permits him to select his timber and treatment with a certainty as to strength and durability that is not exceeded in the case of other structural materials. Engineers of this generation, therefore, may build stronger and more durable structures with less timber than their predecessors. The paper under discussion shows what the past generation could do.

It is a fact which will probably be questioned by few who are conversant with present practices, that frequently advantage is not taken of the information now available. The Highway Department of one important State is now using timber grading rules and specifications written thirty years ago, and an important city is using creosoting specifications nearly as old. This is a waste of money.

Men like Timothy Palmer whose bridges are described in the paper, were in advance of their time. This generation of engineers may well ask themselves whether in their frequent disregard of the oldest and one of the best of the available structural materials, they are worthily "carrying the torch of progress."

H. FUGL MEYER,[85] ASSOC. M. AM. SOC. C. E. (by letter).—A brief statement as to the contribution of the Chinese to the art of bridge building is of importance in establishing the origins discussed in this interesting paper. The Chinese character, "chiao," denoting a bridge, contains in its components the idea of a lofty wooden construction. The character was formed about 1003 B. C., thus lending authority to legendary history, which records the information that the Chinese had undertaken the construction of fairly large wooden bridges at a very early date. From the Confucian annals and from the history of the Near East it is known that in a number of Asiatic countries wooden pontoon bridges of considerable length were in regular use before 600 B. C.

At that early date there were a number of communities with a fairly high civilization in the part of Central Asia that now (1933) forms the western border of China. Because the turbulent and wide mountain streams in this territory made all inter-communication difficult, Nature made the inhabitants bridge builders long before written records of their kingdoms begin.

A number of interesting wooden cantilever and suspension bridges are still to be found in these regions. Whenever the width of the stream is less than, say, 130 ft, a cantilever appears to be preferred. Suspension bridges of plaited bamboo ropes are used for spanning streams as wide as 250 ft.

---

[85] Mgr., Free Port of Copenhagen, Copenhagen, Denmark.

Multiple-span bridges of both types of construction are still extant, the longest being a suspension bridge of 700 ft.

Chinese bridges are generally the principal gathering place for the inhabitants of the neighboring town, and, therefore, they are often covered with a roof or are fitted with supports for a light roof of bamboo matting as a protection against sun and rain. Fig. 45 represents a bridge in the small Tibetan-Chinese Kingdom of Muli. It will be noted that two heavy stone-filled wooden caissons lend stability to the cantilevers. The central part of the span can be removed when the King of Muli finds it necessary to block this entrance to his realm.

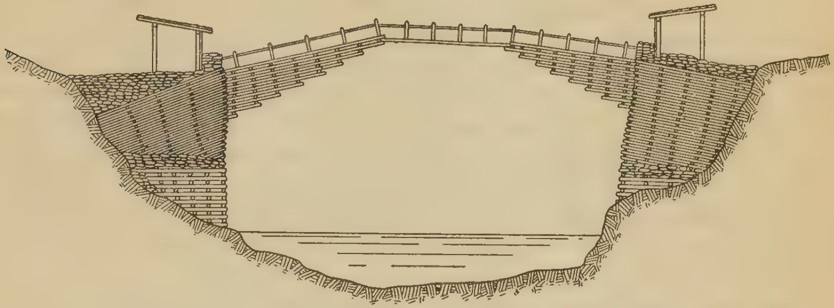

FIG. 45.—CANTILEVER BRIDGE IN THE KINGDOM OF MULI.

W. E. HOWLAND,[86] ASSOC. M. AM. SOC. C. E. (by letter).—In an "Encyclopædia or Dictionary of Arts, Sciences and Miscellaneous Literature," printed in Philadelphia, Pa., for Thomas Dobson, in 1798, and in the "Supplement" published in 1803, several articles appeared relating to wooden bridges, namely, "Arches," "Centering," "Carpentry," "Roofs," and "Strength of Materials," all related one to another with numerous cross-references. This twenty-one volume compilation[87] offers an opportunity for the student of the history of the development of technology to determine what was known about a particular science at a given period, and, in this case, it shows what knowledge might have been carried over from Europe to America. Such a medium as this could have brought to the early American bridge builders the knowledge gained by their European colleagues, not only in building wooden bridges, but also in the science of the equilibrium polygon and in countless practical details of wood construction for carrying heavy loads.

Although, as the authors have pointed out, the European wooden bridges were not especially noteworthy at this time, certain other Continental wooden construction appears to have been developed to a high degree of perfection before the era of American wooden bridge construction, for example, the wooden centering of Perronet and the wooden roof trusses of Sir Christopher

---

[86] Asst. Prof. of Civ. Eng., Purdue Univ., Lafayette, Ind.

[87] Reprinted from "Encyclopaedia Britannica," or a Dictionary of Arts, Sciences and Miscellaneous Literature," Third Edition, printed for A. Bell and C. Macfarquhar, Edinburgh, Scotland, 1797.

Wren. The writers of this encyclopædia assembled this knowledge and made it available in a convincing and understandable form for the potential bridge builder. It seems inconceivable that a reader of these articles would not have profited immensely both in obtaining a clearer mental picture of the principles involved and the manner in which the forces distribute themselves in a complicated frame, but also in adding to his knowledge of practical details of construction.

The article on "Strength of Materials" is a mine of information to the historian of science. Its author considers tension, compression, and shear and the resistances of various materials (particularly wood) thereto. He considers Euler's column theory, and he derives a practical rule for estimating the strength of a beam in bending which is in close agreement with modern ideas; that is, he assumes that the strength varies directly with the breadth of the beam and with the depth squared, and that a beam loaded in the center requires a strength that is proportional to the span and to the load. All the theory presented is discussed in the light of practical knowledge and is translated into rules-of-thumb for the use of the artisan.

The article on "Roofs" contains a discussion of improper practice in joining wooden members, and it ends with the maxim of Perronet, namely, "to make all the shoulders of abutting pieces in the form of an arc of a circle having the opposite end of the piece for its center."[88] Then, to connect this subject of roofs with other phases of wood construction, the author adds this sentence,[89] "much of what has been said on this subject may be applied to the construction of wooden bridges and the centers for turning the arches of stone bridges."

The work of Perronet is discussed in the article on "Centering,"[90] with critical insight and yet with admiration. This section treats of the history of the development of the center to produce the stiffness needed for maintaining the shape of the stone arch in various stages of its construction. The author commends the center used by Mr. Robert Mylne (1734-1811) for the Blackfriars Bridge, at London, England. This bears a striking resemblance to a Bollman truss, with the compression members and tension members reversed. The construction consists of a number of pairs of struts, each one beginning at an abutment and terminating at a joint on the outside of the centering, the entire framework being joined together to form a structure of great rigidity.

In the article on "Carpentry,"[91] the author again refers to the work of Perronet. He states, for example, that:

> "The strongest of all methods of piecing a tie-beam would be to set the parts end to end and grasp them between other pieces on either side * * *. Mr. Perronet used it for the tie-beams or stretchers by which he connected the opposite feet of a center which was yielding to its load and had pushed aside one of the piers above 4 in."

---

[88] "Encyclopædia or Dictionary of Arts, Sciences, and Miscellaneous Literature," 1798, Vol. 16. p. 476.

[89] *Loc. cit.*, p. 480.

[90] *Loc. cit.*, Supplement, 1803, Vol. 3, p. 234.

[91] *Loc. cit.*, p. 212.

The author then describes the use of scarfing employed by Perronet for eliminating bending in the bolts that connect wooden members. Two full pages of these and other joints are included, and two pages of illustrations of roof trusses, one with a clear span of 80 ft, and a sketch of the walking beam truss used by Watt and Boulton on their steam engine. It has tension members for the top chord.

The author on "Centering" discusses disapprovingly the wooden arch built by Grubenhamm, at Wittingten, Switzerland.[92] He then refers with admiration to a "bridge over the Portsmouth river in North America, * * * more than 250 ft in length * * * of several parallel arches of beams." The inventor said to be a Mr. Blodget, is quoted as saying that he found the strength of this bridge so great that he could with perfect confidence make one of four times the span. Could this be the Piscataqua Bridge of Timothy Palmer built in 1794 and referred to by Messrs. Fletcher and Snow?

Finally, in recommending the best form for a wooden bridge, the contributor of this article returns to the ideas of the roof truss and the arch centers, concluding with these significant words:[93]

> "The reader must perceive that we have now terminated in the construction of the Norman roof. We indeed think it the best general form, when some moderate declivity is not an insuperable objection. When this is the case, we recommend the general plan of the centering of the bridge of Orleans. We would make the bridge (we speak of a great bridge) consist of four trusses; two to serve as the outsides of the bridge, and two inner trusses, separating the carriage-way from the foot-paths. The road should follow the course of the lower polygon, and the main truss should form the rails. It might look strange; but we are here speaking of strength; and evident, but not unwieldly, strength, when once it becomes familiar, is the surest source of beauty in all works of this kind."

HARRY K. ELLIS,[94] ESQ. (by letter).—The authors state that "as late as 1930, there were between 450 and 500 covered bridges in use." This must be an under-estimate, because in Chester County, Pennsylvania, alone there are forty-four covered wooden bridges at the present time. Nine were torn down in 1932, so that in this County there must have been at least fifty-three covered bridges in 1930. Many of the other counties in Eastern Pennsylvania still have large numbers of such bridges.

Among the bridges still existing in Chester County is one of 100 ft span, built in 1807 and still carrying traffic, and one of 60 ft span, built in 1819. The latter bridge is shored up at the present time. The writer believes that the one built in 1807 must hold the record for long life of Burr truss bridges, since Burr's first bridge was built only three years earlier.

Most of the covered bridges in Chester County are of the Burr type with the wooden arches extending to a height about 2 ft below the eaves. White pine was used in almost every case. Some of the bridges are of the queen-post type, without diagonals in the middle panel, and with the floor-beams hung upon a single bolt which passed through the center of the floor-beam upward through the lower chord and about 1 ft to 1.5 ft higher through the truss post. A notch cut in the post permitted the insertion of a nut into which the bolt was screwed. Usually, this notch was on the outside of the truss and covered with the siding boards so that inspection was difficult.

[93] *Loc. cit.*, p. 249.

[94] County Engr., Chester County, West Chester, Pa.

It is true that the floors were the weakest part of these bridges, but the writer has twice seen a perfect compression failure of the arch rings. In both cases the wood broomed out on all four sides of the ring at the point of failure. In both cases, the arch was subject to a greatly increased load due to the bridge as a whole being much out of line.

NELSON J. BELL,[95] M. AM. SOC. C. E. (by letter).—This paper is most instructive, especially since technical literature in the past half century seems to have almost wholly neglected the subject. The general opinion among engineers has come to be that the old wooden highway bridges are fit objects of sentimental interest, but of very little practical worth in this age of steel and concrete. The paper by Messrs. Fletcher and Snow should bring home the fact that with only nominal care these old bridges have served their purpose with almost 100% efficiency over periods of 50 to 100 years, and, therefore, may be worthy of close technical study before it is decided whether one should be further preserved for practical use or should be condemned and scrapped. The mortality of these old bridges has been greatly increased in recent years because of the lack of knowledge concerning them and the consequent offhand opinion that they are unsafe under present-day traffic.

The preponderance of evidence brought out in this paper is to the effect that the bridges built by Wernwag, Burr, and most of their imitators, had an excess of strength everywhere except in their floor systems and lateral bracing, but no one has as yet described a method by which the distribution of stresses in the trusses may be analyzed. An exact analysis is probably impossible, and, in any case, would involve so many unknown factors that it would be highly impractical. In some cases it is possible, however, to arrive at a reasonable analysis of the primary stresses in the members by means of assumptions and simple graphic statics.

Several years ago, the writer was employed to investigate a wooden bridge spanning the Kentucky River at Camp Nelson, about twenty miles south of Lexington, Ky. This bridge was built in 1838 by Lewis Wernwag. It has a single span of 240 ft and is composed of three trusses which are identical in all respects, except that the outer ones are curved horizontally so as to form flat arches, equal and opposite to each other. The outer trusses are spaced about 25 ft, center to center, at the middle of the span, and about 30 ft, center to center, at the ends. The center truss is straight and bisects the bridge, forming two one-way roadways. The general design is so similar to that of the bridge over Cheat River, Preston County, West Virginia (Fig. 35), that both must have been designed by the same man. The Camp Nelson Bridge is much heavier, the arches being composed of six pieces, in two rings of three pieces each. There is also a double web system, the main diagonals being composed of two pieces each, passing outside the arch rings, and the single-piece counters passing between the two arch rings. The verticals have three pieces each, the center one passing between the arch rings and the others passing outside. Thus, the arches are clamped against lateral deflection by the verticals and diagonals. The verticals are dapped over the arches and bolted to them, but the diagonals have no connection to the arches, except by friction. An illustrated description of this bridge, with a tabulation of maximum stresses and an outline of the method of analysis was published[96] in 1928 by the writer and J. K. Grannis, M. Am. Soc. C. E.

---

[95] Structural Engr., Dayton, Ohio.

It seems to be characteristic of Wernwag's bridges that they have heavy arches with comparatively light stiffening trusses, and that their ends are anchored to the abutments by tension rods. The Camp Nelson Bridge is composed essentially of three arches, each braced laterally and vertically by a stiffening truss, and the whole tied together with lateral trusses at top and bottom. The points of application of loading on each arch are spaced uniformly along the perimeter of the arch by means of the inclined posts, set normal to the curve of the arch. Dead and uniform live loading, therefore, causes compression in the arch, coincident with its center line. The truss is not stressed except by eccentric loads, under which condition it distributes the loads uniformly to the arch, thus limiting all stress in the arch to compression. The stress distribution can be reasonably compared to that in a suspension bridge, the only difference being that in this case there is an arch in compression instead of a cable in tension. With any eccentric load on the truss, it tends to rotate on the arch. This must be counteracted either by the dead weight of the truss, or by anchoring the ends to the abutments, and it is interesting to note that the trusses of the Camp Nelson Bridge were actually anchored by wrought-iron rods extending from the tops of the end posts down into the masonry.

The trusses by Burr and some others do not lend themselves to stress analysis as readily as those by Wernwag, as they seem to have been designed on the principle of a simple truss aided and strengthened by arches, so that there is no definite place where truss action stops and arch action begins. It would certainly be on the safe side to make the analysis on the basis of a stiffened arch where the arches have adequate lateral and vertical support to prevent distortion, but as the dead loads of these bridges greatly exceed the live loads, it is more practical to assign the dead load to the arches and the live load to the trusses and analyze them separately. In any case, the judgment of the investigator enters largely into the problem, and must supplement the mathematical work.

The main point which the writer wishes to make is that the old wooden bridges should not be condemned and scrapped just because they were not designed with the aid of present-day engineering knowledge and standards. Many of them can be made safe and serviceable for modern traffic by very simple repairs and reinforcement of their floors and lateral bracing systems, at a small fraction of the cost of removal and replacement.

---

[96] *Engineering News-Record,* Vol. 100, No. 6, February 9, 1928, p. 234.

ROBERT FLETCHER[97] AND J. P. SNOW,[98] MEMBERS, AM. SOC. C. E. (by letter).—A gratifying interest is revealed by the number of discussions submitted in connection with this paper. These discussions have brought to light historical matter of great value, and have increased the knowledge of timber bridges still doing good service. They have widened the view of the ancient history and of the later European period. That timber bridges have yet a "reason to be" is amply proved; and their use for some decades seems to be possible. These fruitful results of a suggestion made by other members of the Society constitute an important chapter of the history of the profession, which might have been lost beyond recovery.

Concerning Cæsar's military bridge—to meet the objection that the notched blocks, as the only connectors at the end of the bents, might fail by crushing at the sharp edges, or by splitting between the notches—a model of one span on two bents was made on a scale of one-twelfth that of the prototype. An estimated load on the span to include the weight of the large, rough-hewn green timber and a column of troops, four abreast, carrying arms and accoutrements, was computed to exceed 14 000 lb. By scale reduction the equivalent load on one bent of the model should be in excess of 100 lb (1 to 144). The model sustained two heavy men aggregating nearly 400 lb in weight, on two bents; that is, nearly 200 lb on one bent. After separation, the parts gave no indication of over-strain.

Figs. 46 and 47 are two notable views of Timothy Palmer's Bridge at Easton, Pa. (see Fig. 11), taken after the bridge had been in continuous service for 89 years. These photographs were taken in 1894 by Eugene Mowlds, M. Am. Soc. C. E., just one year before the removal of the bridge to make way for a structure capable of sustaining traffic by trolley cars. These views of the exterior are valuable as showing the care which the master builder exercised to produce a distinctive architectural effect, in contradistinction to the barren, cheap-as-possible housing since adopted in covering wooden bridges. Fig. 46 shows the appropriate covering with pleasing lines, harmonizing with the surroundings and giving a sturdy aspect to the structure as a whole. Fig. 47, a view of the Easton end, shows enough adornment to relieve homeliness; and, above the portal, is the name and date to serve as the signature attesting the authorship.

Under the heading "The Howe Truss," the writers mention as unusual types, two Howe truss bridges with an arch on both sides of each truss, and state that they had no knowledge of any other Howe truss bridges so constructed. In correspondence with the writers, F. J. Nevins, Valuation Engineer, of the Chicago, Rock Island, and Pacific Railroad Company, and Frank F. Fowle, of Frank F. Fowle and Company, Consulting Engineers, of Chicago, Ill., have stated that the first bridge over the Mississippi River was built for the Chicago, Rock Island and Pacific Railroad Company, between Rock Island, Ill., and Davenport, Iowa, during the years 1853 to 1856. It consisted of five fixed spans of Howe trusses, each about 253 ft, with arches on both sides of each

FIG. 47.—ENTRANCE TO BRIDGE OVER THE DELAWARE RIVER, AT EASTON, PA.

truss, and a draw-span. They also state that a second bridge was built a few years later on the same masonry, of Howe trusses having the unusual feature of curved upper chords, and no auxiliary arches. These are historic bridges because of the strenuous and prolonged opposition of the steamboat owners up and down the river to their construction, and because the unbroken railroad connection thus made across the river gave a great impetus to the settlement of the States beyond.

Questions listed in a letter by J. R. Worcester, M. Am. Soc. C. E., with appropriate answers by the writers, are as follows:

Question 1.—Have not arches been found beneficial to abutments, as well as to trusses, in furnishing lateral pressure where most needed?

Answer.—An arch, of course, tends to assist an abutment in resisting the pressure from the filling at its back, but it should not be depended upon to save a weak abutment. An instance is recorded in which a bulging abutment led to collapse of the arch, breaking it at the crown, and buckling the truss. On the other hand, a case is cited of a **T**-abutment with narrow stem, in which buttress masonry behind the heads was needed when arches were added to the bridge.

Question 2.—What is the reason for the different thicknesses of planks shown in Fig. 17?

Answer.—It is wholly to facilitate construction. The customary way to start an arch is to set up light supports on the falsework to define the curve of the intrados and tack $\frac{7}{8}$-in. boards, which bend easily, to them; after which, 2-in. plank (perhaps not so many as shown), are secured to get a solid support on which the 3-in. or 4-in. planks can be clamped and spiked.

Question 3.—Does the working between parts in combined arches and trusses show itself in loosening of joints, in course of time?

Answer.—In lattice bridges the connection between arch and truss is invariably made by vertical rods through the arch and floor-beams or by needle-beams below the lower chords. Any slackness in these rods is corrected by the screw-threads at their ends. This type of connection is advisable with other kinds of truss, but in the Burr trusses of early days the favorite method was to frame the posts to make seats on the arch. The flexibility of timber is such that no serious working at these joints has been observed by the writers. The creaking observed when a train crosses one of these bridges is normal to wooden bridges. It may be caused by warped sticks coming to a full bearing when a load passes over the bridge. It is probably more pronounced in spruce bridges than in those built of white pine, on account of the greater tendency of spruce to warp.

Question 4.—Can you give any figures as to sag of a wooden truss due to shrinkage, and is this less in a Town lattice than in a Howe truss?

Answer.—Sag in wooden bridges is probably not so much due to shrinkage as to compression of surfaces in contact at joints. Lattice trusses without arches naturally sag more than Howe trusses on account of the great number of joints composed of wooden pins in bored holes. This involves pressure on the rough side-grain of pins as well as a tendency to deflection of the pins. To counteract this tendency it is good practice to build 50% more camber into lattice trusses than into those of the Howe type. Howe trusses, if sagged, can be adjusted by setting up their vertical rods. In the lattice type the sag is cumulative. The unique bridge at North Blenheim, N. Y., shown in Fig. 20, has held its camber from 1855 to the present, although it has no vertical truss rods. This is due, without doubt, to the care used in its framing and the seasoning of the timber before framing as noted by Mr. Morse in commenting on the Ninth Street Bridge, in Pittsburgh, Pa.

Question 5.—What units have you found safe for stresses in bolts and treenails in shear? For direct tension and horizontal shear in spruce and yellow pine? Also, in fiber stress in stringers?

Answer.—As is shown in Mr. Guppy's discussion the size of members depends in some cases on connections rather than on longitudinal stress. Unit stresses that have been found, by experience, to result in good practice are listed in Table 1.

TABLE 1.—ALLOWABLE STRESSES IN TIMBER

Description	Yellow pine	Spruce	Oak pins	Iron
Tension	1 000	800	.....	......
Compression	800	650	.....	......
Bending modified by factor containing depth ÷ span	1 200	1 200	.....	......
Bearing end-grain	1 000	800	.....	......
Bearing side-grain, whole width of timber	350	300	.....	......
Bearing side-grain, small area like washers	400	350	.....	......
Shearing, longitudinal	80	80	.....	......
Bearing	.....	.....	400	......
Shearing	.....	.....	600	......
Bending	.....	.....	1 800	......
Floor-beam hangers; tension, net section	.....	.....	.....	7 500
Lower chord coupling rods; tension, net section	.....	.....	.....	10 000
Lower chord gib-plates; bending	.....	.....	.....	12 500
Arch suspender rods; tension	.....	.....	.....	10 000
Lateral rods, loaded chords; tension	.....	.....	.....	15 000
Lateral rods, unloaded chords; tension	.....	.....	.....	20 000

Bridges built to these units have carried loads, the computed stresses from which are twice these units, without showing any ill effects.

Mr. Seaman shows a 2-track jack-knife draw (Fig. 30). The birth and culmination of this type of draw have been shown[69] in *Engineering News-Record,* by a single-track patent drawing and a photograph of the 8-track draw of the Boston and Maine Railroad Company, over the Charles River channel, at Boston, Mass.

Professor Draffin's notice of the Enoch Hale Bridge is appreciated. It was the first in the United States, that could be called a framed bridge, its predecessors having been of the stringer type, none of greater span than could be negotiated with the magnificent pine spars then available. Mr. Hale secured money from Mr. Geyer, a merchant of Boston, mentioned by Professor Draffin, by a mortgage on his toll bridge. It was a well-paying piece of property which Mr. Geyer had been trying to buy for several years. The mortgage was on short time, and, when its expiration approached, Mr. Hale succeeded in borrowing from his friends to liquidate it. He sent the money to Boston by a messenger who dallied a day at Lowell, and when he tendered the funds to Mr. Geyer, was told that he was a day too late, that the mortgage had expired, that Mr. Geyer had already assumed the title, and that the bridge was his. Such was the law of foreclosure in those days, derived from the Cavalier laws of England, the result being that Enoch Hale lost his noteworthy bridge and became indigent in his old age.

---

[69] *Engineering News-Record,* Vol. 108 (1932), p. 93.

Professor Draffin states in his first paragraph that the present concrete successor of the Hale Bridge was built in 1930. The previous lattice bridge was removed in 1930 on account of failure due to a decayed wall block, but the handsome concrete structure was completed and dedicated with fine ceremony in 1932.

The writers concur in Professor Draffin's conclusion that repairs rather than rebuilding were done by Mr. Geyer when the Enoch Hale Bridge was eighteen years old; and that it was done as window dressing in connection with obtaining a mortgage instead of for strengthening the structure. In fact, there is a book extant containing a picture of the village and landscape made from a point at a considerable distance from the bridge, showing its braced stringer outline with the spandrils filled with lattice trim. Probably this trimming with new fences and floor were the extent of Mr. Geyer's repairs. The statement made by President Dwight about the bridge being an obtuse arch has misled several writers. A braced stringer bridge of that magnitude is comparable to a segmental arch of three voussoirs which make obtuse angles with each other. Fig. 8 is an excellent line drawing of the oil painting made soon after the bridge was erected, but the braces were much more sharply inclined than shown, and the right-hand end of the floor should be raised to continue the grade of the other end to meet the side of the gorge higher than indicated. The highway along the mountain side was much higher than the bridge, so that a steep descent was required.

In speaking of the Tucker Bridge (Fig. 18), Professor Draffin calls it of the lattice timber type. This is technically wrong. It was a single-plank lattice bridge of 3 by 10-in. plank, while Fig. 19 is a timber lattice of 6 by 8-in. timbers. Much more of historical interest could be written of this bridge and its contemporary events than is pertinent.

It is gratifying to read in the discussion by Mr. Morse, his appreciation of the splendid workmanship in the bridges built by Theodore Burr. The writers refer to the same characteristic in those built by Timothy Palmer; and indeed it was commented[20] on by the late Theodore Cooper, M. Am. Soc. C. E.

The writers join Mr. Storrs in honoring the early builders who had little to guide them in planning or building their bridges, except their experience and strong common sense. These men and the early builders named in the paper were real engineers. The historians of America have generally ignored them, perhaps because they were regarded as mere carpenters. They were among the "empire builders." They are more deserving of large mention in history and inscriptions on memorial tablets, than many who have achieved less for their country. They are comparable to the "Brothers of the Bridge" who built and maintained the great stone bridges of Europe during the Middle Ages.

The writers can not entirely subscribe to the enthusiasm expressed by Mr. Hogue in the second paragraph of his discussion, as to a recrudescence of timber construction in the country at large; but in regions of primitive growth, as claimed in the paper, they believe a considerable field is open for wooden bridges. The examples of longevity cited for treated lumber (40 years), seems absurd when applied to truss bridges. If properly covered with roof and side boarding 100 years is frequently attained. An example is cited later in this discussion of one, 120 years old, which is still "going strong."

The ring dowels for timber connections mentioned by Mr. Hogue are certainly worthy of consideration. Astonishing examples of their use are illustrated in recent publications of the National Committee of Wood Utilization, U. S. Department of Commerce, Washington, D. C.

The paragraphs of the main paper describing Fig. 16 answer Mr. Oliver's uncertainty in regard to the writers' conclusions as to the adaptability and economy of wooden bridges. Mr. Oliver does not mean that the Selby Bridge, built in 1790, is still in use, as to its original timbers. Stringers bridges last from 5 to 20 years, depending on latitude, character of lumber, and exposure to the weather, but their members are readily renewed, and hence the bridge, as an adjunct of transportation, lasts perpetually. Preservative treatment will double the durability of their members.

Regarding Pons Sublicius, mentioned by Mr. Oliver, the writers do not think any published picture of its construction is authentic.

The writers are greatly indebted to Professor Laurson for the items relating to early European bridges, which he cites. It is interesting to learn that lattice bridges were built on various railroads in England and Ireland previous to 1846. Ithiel Town's patent for this type of bridge was granted in 1820, and it is on record that he visited England about 1840. No doubt he was successful in selling rights to build by his patent. Regarding "assembling" bridges on land before erection in place: If Professor Laurson means assembling them erect, it is seldom, if ever, done. The only practical way to build lattice bridges and others, such as the Burr and Long types, in which the web members pass through the chord, is to frame the trusses lying flat on skids on shore, or on falsework, if wide enough, and traffic is suspended. Holes for pins and bolts are bored in this position and, when complete, each stick is carried to its place on the falsework and assembled erect. The chords of Howe trusses are framed on the falsework and the trusses erected complete after the lower chords are in place. The practice has been to fabricate and erect these bridges as one job; whereas in metal bridges the two phases of the work are widely separated. This distinction may disappear in the Machine Age, supplemented with new methods of making timber connections;

but it is incredible that the building of wooden bridges should become common in regions where organized fabrication shops are within economic reach of the locus of the bridge.

A wrong impression is conveyed by Professor Kirby's reference to the span of the Schaffhausen Bridge (Fig. 7). It consisted of two spans of 171 and 193 ft. The writers have no data showing the span of the McCalls Ferry Bridge, but mention several of much greater span than the Schaffhausen, including some built previous to 1814. (See Wernwag's "Colossus" of 340-ft span, built in 1812 (Fig. 12), and one at Wittingen, Germany, 390-ft span, built during the third quarter of the Eighteenth Century.)[17] It is an interesting fact that a complete model of the Schaffhausen Bridge is still treasured in the town 134 years after the destruction of the bridge by a French army. This is without the covering and exhibits all the details of construction.[100]

Fig. 32, presented with the discussion by Mr. Thompson, is very interesting. The weather protection mentioned by him can be seen to consist of a kind of flexible shingle applied to each stick of the corbels and cross-ties. The presence of this bridge in far Japan, coupled with the numerous examples of the same type now existing in Northern India, and the Savoy ruin, mentioned in the paper, under "The Ancient Background," seem to prove that the corbelled bridge was known and used across the great Eurasian Continent in the early ages of human development.

Mr. Guppy calls attention to an interesting and true phase of the difference in designing wooden and metal bridges. The comparison might be extended to a somewhat similar difference in fabricating and erecting the two classes. Fig. 23, or its modification, might well be added to Figs. 16 and 28 as examples of the use of metal splices in timber tension members.

The simple method of anchoring a bridge to its abutments described by Mr. Houk, is well worth using on all wooden bridges over streams subject to high water or severe winds. Hundreds of wooden bridges have been floated —pushed by drift or blown by wind—from their bearings, nearly all of which would have escaped serious injury had they been anchored. It seems scarcely necessary to carry the rods to the upper chord. A short rod each side of the lower chord, passing through a yoke block, and each one connecting with two wire lines below, would seem simpler to install than the arrangement described by Mr. Houk.

The combination wood and steel bridges described by Mr. Baker are interesting examples of history repeating itself under new conditions. Mr. Baker's type of construction suggests great possibilities for highway bridges of spans up to 80 ft. Lower chords of channels in one length up to two cars long, with perhaps a plate reinforcement at the center, with angle-blocks and tie-plates riveted on at the shop, or laminated chords of treated plank securely united as one timber with ring dowel, or other connectors, would naturally follow as a type of construction suggested by Mr. Hogue. Preservative treatment is not needed if the ends are protected from dirt accumulations, and if treated wall-blocking is used. Rod verticals and timber upper chords and web diagonals may be used. All spans greater than 45 ft should be housed with roof and side covering, using a roof with a good overhang and a pitch of about 4 in. per ft. Inexpensive trim on facade and sides should be used, and the entire structure painted appropriately to present a bungalow appearance, far surpassing in picturesqueness those of the New England covered type. Shorter spans with lower trusses should have each truss housed, roof and sides. A concrete floor-slab on steel cross floor-beams would prevent the decay complained of, and housing will save the end posts and upper chords. Window openings (see Fig. 13), admit light and increase safety of traffic inside, better the appearance outside, and assist ventilation. The flooring, of whatever character, furnishes adequate lower lateral bracing. The upper chords should be adequately braced in connection with the roof framing.

---

[100] An excellent view of the model appears in Mohringer's "Bridges of the Rhine", pub. in 1931.

The writers disagree with Mr. Baker in his statement that wooden bridges are very costly to maintain. It is inferred that the tendency to decay is the cause of his complaint. Piles in sea water, infested with marine insects, open stringers, and plank floors, and, in fact, all timber exposed to the weather, or in contact with masonry or earth, are short-lived in warm climates unless thoroughly treated with a preservative. Truss bridges on the contrary are very durable if protected by housing. (Note the many instances cited in the paper and discussions of bridges a century and more old.) An experience of more than forty years has taught the writers that current maintenance of wooden truss spans is not so costly as maintenance of steel spans. The worst enemy of wooden bridges is fire, due at present largely to cigar and cigarette stubs. Obsolescence and increase of loads, especially in case of railroads, are the usual cause of renewals, rather than physical defects.

Mr. Reed and Messrs. Davis and Jemison have furnished valuable records of early truss bridges west of the Allegheny barrier. These trusses as a whole are based on the Burr design, a worthy example to follow.

The Ramp Creek Bridge built about 1837, with its arches, upper chords, and roof framing of yellow poplar (white wood), and its floor-beams, stringers, and under floor of walnut, causes surprise to an Easterner; but it really shows excellent engineering judgment on the part of its builders and was not less remarkable than the use of the magnificent white pine for bridge work in the East, which timber was once reserved, by law, for masts of the Royal English Navy. The fact that after about 95 years of service the bridge was deemed worthy of re-erection in a location where it would be subject to no heavier traffic than that for which it was built, is certainly worthy of attention.

Failure of floor-beams by longitudinal shear is common if they are overloaded and mortised near their ends for lateral braces, as described for the bridges in Figs. 35 and 37. A well-laid floor is very ample for lateral bracing of a highway bridge. The "bowing" out of line mentioned in the case of the former bridge is quite likely due to flatness of arch and lack of rigidity of the shallow truss with no counters.

The durability of the hand-forged bolts mentioned in the description of this bridge is worthy of note, although not strictly pertinent to a paper on wooden bridges. The more nearly pure an iron is, the better it resists corrosion. Old-time Swedish or Russian iron, or present-day ingot iron, is practically rust proof; while structural steel is not so durable as wood in certain locations.

The Kennedy family, J. J. Daniels, and Lemuel Chenoweth, should be added to the honor roll of names of noted bridge builders.

Another variation of the Burr type of truss was seen in a bridge built by George W. Thayer, of Massachusetts, over the Delaware River, at Narrowsburg, N. Y., in 1859, which had the longest framed trusses (clear span of 262 ft), except Wernwag's "Colossus" (see Fig. 12), of which the writers have knowledge.[101] Each truss had two arches on each side, one above the other, separated by 12 in., or more. A peculiarity in the trusses was horizontal struts ("straining pieces") between the posts, fixed just below the upper, and above the lower, chords where the diagonal braces were framed into the posts. The latter feature was specified in a patent granted to Mr. Thayer in 1845.[102] This and other patents noted in the paper are illustrated and described in a series of articles,[103] by F. B. Brock, Patent Attorney, Washington, D. C., on expired patents for wooden, iron, and combination bridges. The Narrowsburg Bridge was removed when it was about forty years old, while still capable of giving good service (probably for more than twice that period).

The "modern" timber connectors shown by Mr. Landsem are interesting. The multitude and variety of these patented connectors reminds one of the flood of United States patents issued prior to 1880 for bridge trusses of wood, iron, and combinations of the two, each patentee claiming that his arrangement of parts was safer and cheaper than any previously proposed system. The upper chord joint (Fig. 41), seems like a substitute for the American pin-joint. By hooking the four members to a ring in this joint there is no moment induced on the center bolt. Its workmanship must be quite expensive. On this account it is not probable that this joint will be generally used in this country. There is a wide field for their use as smaller connectors in high towers of timber trestles, towers for transmission lines and radio aerials, and especially for portable structures, such as oil-well drilling derricks, observation stands, etc. The old-time rectangular key, with a length of about ten times the depth of dap cut in the timber for it, and two bolts to resist the overturning tendency, is ideal in efficiency, but is perhaps not so economical in these days of machine employment as the circular dap and connector. A simple disk with a central bolt is probably the best solution of the problem.

Mr. Landsem has contributed some valuable facts as to European bridge building, ancient and modern. His statement about the flexibility of laminated arches should not deter builders from their use. If properly secured to stiffening trusses they hold their shape perfectly. Mr. Landsem mentions the materials as being "boards." Arches are built up of 2 to 4-in. "boards" very readily. Radial bolts should be inserted at intervals of not more than 8 ft, and the load applied at points should not be more than 12 ft apart. If greater intervals are allowed buckling may occur.

[103] *Loc. cit.*, Vols. 9 and 10.

Professor Finch contributes a fine historic summary—a splendid frame in which wooden bridges occupy but part of the picture. There is little in it for the practical bridge builder to discuss, but the writers feel disposed to comment upon the feature of statical indetermination and the men named as bringing American practice to rational analysis.

It is a fact that the two all-wooden types best adapted for bridges are inherently statically indeterminate; namely, the Burr (Figs. 14 and 15), and the lattice with supplementary arch (Fig. 17). The elasticity of the material, the tolerance of timber joints to slight distortion, and the natural law of gravitation will bring the stress to the most rigid members. Timothy Palmer's Easton bridge (Fig. 11), was a rather indifferent truss yoked to a flat arch for a lower chord. Theodore Burr improved on this, introducing more indeterminacy but also a large amount of practicality, resulting in wide adoption and approval, as shown throughout this paper and its discussion. The lattice with arch is superior to the Burr type in that it requires much simpler forms of timber, much less skilled labor, and its truss is much better adapted to resist reversals of strain. Still the rank indeterminateness is there, and no one but the schoolmen know or care anything about it. If there is strength enough in both members of the combination acting together, the elasticity and safe "give" at joints will distribute the load exactly according to the static rigidity of each.

Regarding the men named by Professor Finch: Colonel Long was a bridge builder of courage and imagination, although his designs were not so extensively copied as were those of Burr, Town, and Howe. Neither Ithiel Town nor William Howe were builders of bridges. Town was a business man who patented the lattice type which was designed and built in Vermont years before the patent was issued. Sanford Granger, mentioned in the paper, was probably connected with Mr. Town, in securing the patent. Mr. Granger, however, did not invent the type. A lattice bridge was built in 1813 (when Granger was only 17 years old) over Otter Creek, in Pittsford, Vt., many miles from his home. The bridge is still in service after 120 years. It was thought worthy of being floated up river to its place in 1927 when the high water of that year carried it a mile or more from its abutments. Town also patented the timber lattice in 1839. This is also of Vermont birth. William Howe was an architect. In 1839, in connection with Amasa Stone, then 22 years old, he built a bridge of 75-ft span for the City of Springfield, Mass., probably on the Howe principle, because in 1840 he secured a patent, and they built the great bridge over the Connecticut River (Fig. 24), as stated in the paper. The next year Stone bought out Howe's rights in the patent and went into bridge building as a business. Later, he formed a company under the name of Stone and Boomer which engaged in railroad and bridge construction on a large scale.

Concerning the reference to Trajan's Bridge over the Danube River by Mr. Eremin, the figures quoted are those given by Nicholas Bergier[16] and Dion

Cassius.[104] The latter was the Roman historian whose notable history of the Roman Empire in eighty books was written between 217 and 229 A. D.—the century following Trajan's death in 117 A. D.[105] The historian's account of this prodigious and unprecedented work states that it was built to facilitate Trajan's second campaign against a revolted enemy, who killed himself after complete defeat in 106 A. D. The same authority puts the building of the bridge about 104 A. D. The brief existence of the bridge is also noted, for the narrator adds that Trajan's successor, the Emperor Hadrian, caused the arches to be torn down because he was extremely jealous of the fame which this 'wonder of the world"—as the narrator styles it—had brought to his predecessor.[106]

The information on foreign bridges contributed by Messrs. Eremin and Andersen is highly appreciated. The double-web systems of the Gulfoss and other bridges of the Howe type are interesting. They admit the use of smaller diagonals and rods than single systems but, for spans such as those mentioned, it is doubtful if the added work of framing and assembling did not more than balance the saving of material. The omission of side boarding seems wasteful. The lower chord needs protection from the elements more than the upper one. The type of trestle shown was formerly used in some sections in the United States and has the advantage, if properly designed, of allowing the removal of any piece of timber for replacement without interrupting traffic.

Northern Russia and Scandinavia with their wealth of coniferous timber growth are the natural homes of the lattice type of bridge. Baltic fir is well adapted for that type if proper units of stress are used. One-inch round iron or steel drift-bolts, instead of the oak pins shown on Fig. 16, would be advisable for connectors.

The suggestion of Mr. Atwood that early obsolescence may overtake a structure built for all time is of much greater moment than many realize. Most engineers have dug out so much that their predecessors built under the slogan, "build for the future"—good, durable, and expensive work no doubt, but ill adapted to present-day needs—that they should feel that their work will probably go the same way, and that they should build simply what is needed now, and pay for it. The other alternative is to do as has been done many times, to wit, build for the future, paying for it with bonds for coming generations to liquidate long after the constructions have been abandoned or dismantled.

Mr. Meyer presents another specimen of the interesting type of corbelled bridges which have appeared at several points in this paper and its discussions. The great heart of the Eastern Continent lying east of the Ural Mountains and including Western China, in which the Kingdom of Muli is situated, has much to reveal of the early history of Aryan peoples. This type of bridge, called "cantilever" by Mr. Meyer, must be accepted as the prototype of constructed bridges. It is found from the Pacific to the Atlantic Oceans, coming to Europe, apparently, with the Alpine stock of people in very ancient times. Its class had better be called "corbelled," leaving "cantilever" to the distinctive type with the back lever doing duty by spanning an opening.

[106] Bergier's "Histoire, des Grandes Routes de l'Empire Romain," Tome 2, livre 4, p. 750.

Professor Howland submits some appropriate information about the engineering literature available in the Eighteenth and early Nineteenth Centuries. It recalls research made for the paper, the results of which were precluded because of limitations of space. The lack of suitable timber in England, and the resort to cast iron by the English engineers was noted in the paper under "Later European Timber Bridges." For example, this appears by consulting the monumental folio atlas accompanying Rickman's "Life of Telford." That portrays, by fine engravings, 22 stone bridges, including masterpieces such as the famous London bridges; 35 road bridges in the Highlands of Scotland—from arched culverts to those of two or more spans—all of stone; 8 bridges built of cast iron, made in sections and bolted together—two over the Thames and others less known; 2 famous suspension bridges; and only 2 timber bridges of minor importance.

Turning to the European Continent a different story comes to light. The treatises on "The Arts of Construction and Carpentry" by French engineers—Gauthey, Bélidor, Bruyére, Cordier, and especially E'my—are prolific in fine drawings of actual or suggested timber bridges in a great variety of arched and braced contrivances. Perronet, who made his great stone bridges patterns (as it were) for English engineers and the world to follow, developed the designing—as Professor Howland has described—of the heavy timber centers which he required. It is in order to add that the splendid atlas of plates portraying his works has only one drawing of a timber bridge, and that was a "project" for a bridge over the Seine, in Paris, with seven arches of 60-ft span and 10-ft rise, on piers of timber piles. Evidently, he preferred to build for posterity.

Mr. Ellis corroborates others in showing the general prevalence of the Burr type of bridges in certain sections of the country. In some others, particularly in Northwestern New England, the Town lattice prevailed. Burr's designs were not conspicuous for scientific proportioning of parts. His experience and natural flair for heavy construction were probably his only guides. The later changes in character of highways and of loads carried, would find weak spots in many of his bridges, especially those built by others who had not his flair and who built at his type rather than to it. The combination truss and arch, which is the real essence of the Burr patent as finally adjusted, is the absolute final acme of design in wooden bridges of considerable span.

Mr. Ellis adds cumulative evidence to the value of effective covering which is stressed strongly in the main paper.

Mr. Bell's discussion opens an interesting line of conjecture. He states that the bridge at Camp Nelson, near Lexington, Ky., was built by Lewis Wernwag in 1838, and he feels certain that the one at Cheat River (Fig. 35), was constructed by the same builder. In 1855, Nicholas Powers built the

North Blenheim Bridge (Fig. 20), using the same principle of construction—an arch of three rings on the center line of the truss—but he carried his middle truss to the ridge pole of the pitched roof, which brilliant idea, was missed by Wernwag, both at Cheat River and at Camp Nelson. Powers adopted the later type of Long's patent truss which is better adapted for stiffening the arch than the Burr type. The arches of these three bridges follow those of Wernwag's famous "Colossus" in design, but in these later designs he adopted the parallel chord idea of Burr for the stiffening truss instead of framing it on top of the arch (see Fig. 12), thereby giving better support for floor and roof than the original example.

Without doubt the first example of an arch on the center line of a truss was at the Cheat River Bridge, and its author was Lewis Wernwag, who died at Harpers Ferry, Va., in 1843. The two examples show that he adopted, as his later practice, the arch as the main carrier of loads, placed on the center line of the truss designed to hold it from distortion under concentrated loads, even to the extent of the twin arches embedded in a single truss, as at Camp Nelson. His arch segments were hewn to the curve of the arch. This involves the weak factor of timber (longitudinal shear) to a slight extent; and laminated arches laid up with planks 3 to 4 in. thick are now generally used. It remains to examine the truss factor to determine the best type to use for the heavy concentrated loads of the present time both for highway and railroad service. Manifestly, a truss, all the members, chords, and web of which will act in tension or compression, is ideal for the purpose. The Town lattice fills these requirements perfectly, and hence must be given preference. It is gratifying that the idea can be traced back to the illustrious Wernwag.

The sentiment expressed so strongly by Mr. Bell that wooden bridges should not be scrapped because of obsolescence and possibly weak floors, is heartily seconded and upheld by the writers.

Considerable has been written in these discussions about preservative treatment of timber for various purposes connected with bridges. In other publications, treated timber for heavy truss bridges of long span, has been advocated so that roofs and side covering would not be needed. The advisability of the use of preservative to this extent has not been proved either by the discussions or by the experience of the writers. For trestles, small deck spans, and short spans unsuited for covering, treated timber is advisable; but for trusses of spans requiring joints in lower chords, covering is demanded. Esthetic reasons, as well as economy require covering of trussed spans. What looks worse in a landscape than an uncovered wooden through truss bridge especially if it is black with preservative? The bridge shown in Fig. 29, for example, was rightly left uncovered for temporary use only; but its unfinished aspect shows how those designed to be permanent would look.

The general trend of these discussions amply proves the longevity of wooden bridges and justifies their use in localities where they are substantially cheaper than bridges of metal or masonry.

A chronology of the development of the types described in this history and its discussion is given herewith; the first twenty-three types, in this list, built during a period of nearly fifty years, were framed by use of treenails and such small hardware as could be forged by blacksmiths:

Pile-trestle and stringer bridges, crib and stringer bridges after European antecedents	From 1620 forward
Enoch Hale's braced-stringer bridge, at Bellows Falls, Vt.	1785
Timothy Palmer's Essex Merrimac Bridge	1792
Timothy Palmer's Piscataqua and Haverhill Bridges	1794
Timothy Palmer's Georgetown, D. C., Bridge	1796
Timothy Palmer's "Permanent" Bridge, at Philadelphia, Pa	1804–06
Timothy Palmer's Easton, Pa., Bridge	1805–06
Graves' (second) Connecticut River Bridge, at Hanover, N. H.	1796
Windsor, Vt., Bridge, contemporary with the Graves' Bridge	1796
Theodore Burr's Waterford, N. Y., Bridge	1804
Theodore Burr's Trenton, N. J., Bridge	1806
Theodore Burr's Mohawk River Bridge	1808
Theodore Burr's Harrisburg, Pa., Bridge	1816
Lewis Wernwag's "Colossus" at Philadelphia, Pa.	1812
Lewis Wernwag's New Hope, Pa., Bridge	1813–14
Lewis Wernwag's "Economy" Bridge	1810
Earliest lattice-truss bridge of which there is record	1813
Ithiel Town's plank lattice truss, patented	1820
Truss of Stephen H. Long, patented	1830
Ithiel Town's timber lattice truss, patented	1839
Wernwag's Cheat River Bridge, West Virginia	1834
Wernwag's Camp Nelson Bridge, near Lexington, Ky. (Standing in 1933 after 95 years. In both these bridges the arch is on the center line of the truss.)	1838
The Ramp Creek Bridge, Indiana, Burr trusses, built in (Renovated and in service, 1933, after 96 years.)	1837
The Raccoon Creek Bridge, Indiana, Burr trusses. (Still in use, 1933, after 95 years.)	1838
Brunel's experiments in England with preservatives, kyanizing, etc.	1835
Wooden lattice bridges on British railways after Ithiel Town's visit about 1840, before	1846
William Howe's patent for the Howe truss	1840
William Howe's Connecticut River Bridge, at Springfield, Mass.	1840

The Tucker Bridge, at Bellows Falls, Vt., plank lattice	1840
The trusses of Thomas W. and Caleb Pratt, patented	1844
Typical Burr truss railroad bridge (framed with white pine), at White River Junction, Vt.	1848
Howe truss bridge with double arches, at Bellows Falls, Vt.	1850
The unclassified truss of Nicholas Powers, North Blenheim, N. Y.	1855
First bridge across the Mississippi River, five spans, Howe trusses with double arches, at Rock Island, Ill.	1853–56
Second historic bridge at Rock Island, Ill., Howe trusses with curved upper chords and no arches, some time before	1868
The Ledyard Bridge, at Hanover, N. H., timber lattice	1859
Howe truss bridge with double arches (12 spans) at Havre de Grace, Md.	1862–66
The gallows-frame drawbridge	1660
The **A**-frame drawbridge	1835
The jack-knife drawbridge	1845

Within less than a month after publication in "Proceedings" of the closure of the discussion on "A History of the Development of Wooden Bridges," Mr. Snow, joint author of the paper with Professor Fletcher, died suddenly on September 4, 1933, in his eighty-fifth year. His associate in the research can do no less than testify that whatever of authoritative value this paper may possess, is due in very large measure to Mr. Snow's part in its production. Mr. Snow's long experience as Bridge Engineer and, later, as Chief Engineer of the Boston and Maine Railroad—covering the period when wrought iron gradually superseded timber in bridge construction—made him an outstanding authority on the subject. His knowledge of details and his experience in maintenance of such bridges constrained him to adopt a conservative policy in retaining timber bridges as long as they could be made assuredly safe under increasing loadings.

Paper No. 1865

DISTRIBUTION OF SHEAR IN WELDED CONNECTIONS

By Henry W. Troelsch[1], M. Am. Soc. C. E.

With Discussion by Messrs. F. T. Llewellyn, A. S. Woodle, Jr., Milton Male, William Hovgaard, Charles W. Chassaing, F. E. Fahy, W. H. Jameson, P. Wilhelm Werner, Isamu Ohno, and Henry W. Troelsch.

Synopsis

The purpose of this paper is to analyze mathematically the distribution of shearing stress along the length of longitudinal fillet welds used for connecting structural members. The analysis will be made only for welds that are continuous over the entire length of a lap-joint. In an approximate manner, however, it will apply also to intermittent welds. It can also be used to show the approximate distribution of shear in a line of rivets, provided the deformation or slip of each rivet is assumed to be proportional to its shear.

This paper was prepared in 1929 in an endeavor to interpret theoretically the results of a small number of tests made by the Bureau of Standards in co-operation with the American Bridge Company. Since then several other experimental investigations dealing with the same subject have been undertaken, and it is felt that the mathematical analysis will be of sufficient interest to warrant its publication.

Assume that two members, carrying either tension or compression, each made up of one or more bars of equal section, are spliced by lapping the bars of one member over those of the other in a symmetrical arrangement, and that they are joined by longitudinal fillet welds extending the full length of the lap. Such a splice is shown in Fig. 1.

Note.—Published in November, 1932, *Proceedings*.

[1] Designing Engr., Am. Bridge Co., New York, N. Y.

Fig. 1(*c*) is a diagrammatic representation of this joint, in which, for simplicity in analysis, each member is shown as a single bar. It will be assumed that at any section, *f-f*, the stress in each bar is distributed uniformly over that bar, and that there is no tension or compression in the weld metal. The welds, as well as the metal of the bars, will be assumed to deform according to Hooke's law. The shearing deformation of the weld at any point will then be proportional to the shearing stress per unit of length at that point. This may be expressed by the formula,

$$q = \frac{v}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which, q is the shearing deformation of the weld; v, the shear per unit of length of weld; and D, the "detrusion ratio," or the measure of the stiffness of the weld. The value of D depends on the nature of the weld, and must be determined experimentally. It will be measured in the same units as the modulus of elasticity, or unit stress.

(c) SIMPLIFIED SECTION

FIG. 1.

The stress in Bar 1 is zero at A and increases to a maximum at B. Similarly, the stress in Bar 2 is zero at B and maximum at A. At some intermediate point, O, the unit stresses in the two bars will be equal and the bars will have equal unit deformations. Proceeding from O toward A the stress in Bar 1, and, consequently, the deformation, becomes constantly less, while in Bar 2 they grow constantly greater. It follows that the displacement between the bars becomes greater as the distance from O increases. Since this displacement is the shearing deformation in the welds, the shear in the welds increases from O to A. Similarly, the shear will increase from O to B. It is evident, therefore, that the minimum shear will occur at O, where the unit stresses in the two bars are equal.

Taking this point, O, as the origin of co-ordinates, let,

a_1 = cross-sectional area of Bar 1.
a_2 = cross-sectional area of Bar 2.
s_1 = unit stress in Bar 1 at any Section *f-f*.
s_2 = unit stress in Bar 2 at Section *f-f*.
E = modulus of elasticity in tension and compression.
N = the number of welds in the joint.
z = the length of the joint.
x_1 = distance of O from the spliced end of Bar 1.
x = abscissa of Section *f-f* with reference to O.
P = total stress (taken as tension) transmitted by the joint.

Consider now that part of the spliced member on one side of Section *f-f*. Since the sum of all horizontal forces must be zero, $s_1 a_1 + s_2 a_2 = P$; whence,

$$s_2 = \frac{P - s_1 a_1}{a_2} \qquad \text{(2)}$$

Take a second section, *f′-f′*, at a distance, dx, from *f-f*, and consider that part of Bar 1 which lies between the two sections (Fig. 1(*d*)). This piece is subject to a tension, $s_1\ a_1$, at Section *f-f*, a tension, $(s_1 + ds_1)\ a_1$, at Section *f′-f′*, and a shear, $N\ v\ dx$, along the welds. From the equilibrium of horizontal forces: $s_1\ a_1 + N\ v\ dx = (s_1 + ds_1)\ a_1$, from which,

$$v = \frac{a_1}{N}\ \frac{ds_1}{dx} \qquad \text{(3)}$$

Substituting this value for v in Equation (1), the shearing deformation is found to be,

$$q = \frac{v}{D} = \frac{a_1}{N\,D}\ \frac{ds_1}{dx} \qquad \text{(4)}$$

Consider now the deformations of those parts of each bar and the welds that lie between Sections *f-f* and *f′-f′*. Under the action of the tensile stress the length, dx, will increase to $dx\left(1 + \frac{s_1}{E}\right)$ for Bar 1, and to $dx\left(1 + \frac{s_2}{E}\right)$ for Bar 2. The increment of the shearing deformation in the distance, dx, will be dq, and the deformation, q, at Section *f-f* will change to $q + dq$ at Section *f′-f′*. These relations are shown in Fig 1(*e*), from which it is evident that $q + dx\left(1 + \frac{s_1}{E}\right) = q + dq + dx\left(1 + \frac{s_2}{E}\right)$; whence,

$$\frac{dq}{dx} = \frac{s_1 - s_2}{E} \qquad \text{(5)}$$

By differentiating Equation (4),

$$\frac{dq}{dx} = \frac{a_1}{N\,D}\,\frac{d^2 s_1}{dx^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6)$$

Equating these values of $\frac{dq}{dx}$ and substituting for s_2 its value from Equation (2),

$$\frac{d^2 s_1}{dx^2} = \left(\frac{a_1 + a_2}{a_1 a_2}\right)\frac{ND}{E}\,s_1 - \frac{P}{a_1 a_2}\,\frac{ND}{E} \quad\ldots\ldots\ldots\ldots(7)$$

The integral of this is,

$$s_1 = K_1 \sinh\frac{x}{b} + K_2 \cosh\frac{x}{b} + \frac{P}{a_1 + a_2} \quad\ldots\ldots\ldots\ldots(8)$$

in which,

$$b = \sqrt{\frac{a_1 a_2 E}{(a_1 + a_2)\,ND}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(9)$$

In Equation (8), K_1 and K_2 are two constants of integration, the values of which are found as follows: From Equations (3) and (8):

$$v = \frac{a_1}{N}\,\frac{ds_1}{dx} = \frac{a_1 K_1}{Nb}\cosh\frac{x}{b} + \frac{a_1 K_2}{Nb}\sinh\frac{x}{b} \quad\ldots\ldots\ldots(10)$$

Since the origin, *O*, is at the point of minimum shear, $\frac{dv}{dx} = 0$ when $x = 0$; whence, $\frac{a_1 K_1}{N\,b^2}\sinh 0 + \frac{a_1 K_2}{N\,b^2}\cosh 0 = 0$. As $\sinh 0 = 0$ and $\cosh 0 = 1$, this reduces to $\frac{a_1 K_2}{N\,b^2} = 0$, or $K_2 = 0$. Equation (8) then becomes,

$$s_1 = K_1 \sinh\frac{x}{b} + \frac{P}{a_1 + a_2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(11)$$

At *A*, where $x = -x_1$, all the stress is carried by Bar 2, and $s_1 = 0$; hence, $0 = K_1 \sinh\frac{-x_1}{b} + \frac{P}{a_1 + a_2}$, or,

$$K_1 = \frac{P}{(a_1 + a_2)\sinh\frac{x_1}{b}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(12)$$

At *B*, $x = z - x_1$, and all the stress is carried by Bar 1. Hence $s_1 = \frac{P}{a_1}$, and from Equations (11) and (12),

$$\frac{P}{a_1} = \frac{P}{(a_1 + a_2)}\,\frac{\sinh\frac{z - x_1}{b}}{\sinh\frac{x_1}{b}} + \frac{P}{a_1 + a_2} \quad\ldots\ldots\ldots\ldots(13)$$

Expanding $\sinh\frac{z - x_1}{b}\left[= \sinh\left(\frac{z}{b} - \frac{x_1}{b}\right)\right]$, multiplying by $\frac{(a_1 + a_2)}{P}$, and reducing,

$$\tanh \frac{x_1}{b} = \frac{a_1 \sinh \dfrac{z}{b}}{a_2 + a_1 \cosh \dfrac{z}{b}} \quad \text{.....................(14)}$$

which serves to determine x_1 and to locate the origin, O.

From Equations (10) and (12), and from the condition that $\frac{a_1 K_1}{N b^2} = 0$,

$$v = \frac{P a_1}{N\,(a_1 + a_2)\,b} \; \frac{\cosh \dfrac{x}{b}}{\sinh \dfrac{x_1}{b}}$$

Multiplying the numerator and the denominator by b, and substituting for b^2 its value from Equation (9),

$$v = \frac{Pb}{a_2} \; \frac{D}{E} \; \frac{\cosh \dfrac{x}{b}}{\sinh \dfrac{x_1}{b}} \quad \text{.........................(15)}$$

The minimum shear occurs where $x = 0$, and has the value,

$$v_{\text{min.}} = \frac{P b D}{a_2 E \sinh \dfrac{x_1}{b}} \quad \text{.........................(16)}$$

The shear will be maximum at the ends of the joint, that is, where $x = -x_1$ and where $x = z - x_1$. When $x = -x_1$, Equation (15) becomes $v_1 = \dfrac{Pb\,D}{a_2 E \tanh \dfrac{x_1}{b}}$, in which, v_1 is the shear at A. Giving $\tanh \dfrac{x_1}{b}$ its value from Equation (14),

$$v_1 = \frac{P b D}{a_2\,E} \left[\frac{a_2 + a_1 \cosh \dfrac{z}{b}}{a_1 \sinh \dfrac{z}{b}} \right] \quad \text{.................(17)}$$

Similarly, letting $x = z - x_1$, and letting v_2 denote the shear at B,

$$v_2 = \frac{P b D}{a_1\,E} \left[\frac{a_1 + a_2 \cosh \dfrac{z}{b}}{a_2 \sinh \dfrac{z}{b}} \right] \quad \text{.................(18)}$$

From Equations (17) and (18), the maximum shears can be found without finding the value of x_1.

The quantities, $\dfrac{a_2 + a_1 \cosh \dfrac{z}{b}}{a_1 \sinh \dfrac{z}{b}}$ and $\dfrac{a_1 + a_2 \cosh \dfrac{z}{b}}{a_2 \sinh \dfrac{z}{b}}$, in Equations (17) and (18) are always greater than unity, and approach unity as a limit as z increases. Therefore, it is impossible by increasing z to decrease the end shears below the following limiting values:

$$v_1 = \frac{Pb}{a_2} \frac{D}{E} \quad \text{.........................(19)}$$

and,

$$v_2 = \frac{Pb}{a_1} \frac{D}{E} \quad \text{.........................(20)}$$

In ordinary cases the limit is approached rapidly; for example, if a_1 and $a_2 = 4$ and $\dfrac{z}{b} = 12$, $v_1 = 1.0000123$ times the limit.

In making tests to determine the detrusion ratio, D, it is desirable to measure the shearing deformation at the points where the actual value of the shear is equal to the average value over the entire length of the joint. Let x_a be the abscissa of such a point. The average value of the shear is $\dfrac{P}{Nz}$. Then, from Equation (15),

$$\frac{P}{Nz} = \frac{Pb}{a_2} \frac{D}{E} \frac{\cosh \dfrac{x_a}{b}}{\sinh \dfrac{x_1}{b}} \quad \text{.....................(21)}$$

from which,

$$\cosh \frac{x_a}{b} = \frac{E}{D} \frac{a_2}{Nbz} \sinh \frac{x_1}{b} = \frac{b\,(a_1 + a_2)}{a_1\, z} \sinh \frac{x_1}{b} \quad \text{........ (22)}$$

Equation (22) gives two values of x_a which are numerically equal but of opposite sign.

The direct stress at any point in Bar 1 is given by Equations (11) and (12), whence.

$$s_1 = \frac{P}{a_1 + a_2} \left[\frac{\sinh \dfrac{x}{b}}{\sinh \dfrac{x_1}{b}} + 1 \right] \quad \text{................ (23)}$$

Substituting this value of s_1 in Equation (2) and reducing, the stress in Bar 2 is found to be,

$$s_2 = \frac{P}{a_1 + a_2} \left[1 - \frac{a_1 \sinh \dfrac{x}{b}}{a_2 \sinh \dfrac{x_1}{b}} \right] \quad \text{...............(24)}$$

In using these equations it is to be noted that x is negative when measured to the left of the origin.

EXAMPLES

Example 1.—Cross-Sectional Area of Bar 2 Twice That of Bar 1.—Let $a_1 = 4$ sq. in.; $a_2 = 8$ sq. in.; $P = 64$ kips; $N = 4$; $z = 6$ in.; $b = 1.153$; $\frac{z}{b} = 5.21$; $E = 30\,000$ kips per sq. in.; and $D = 15\,000$ kips per sq. in. Fig. 2 shows the results of applying the foregoing equations to this case. By Equations (19) and (20) the limiting values of v_1 and v_2 are found to be 4.61 and 9.22 kips per lin. in., respectively, which are only slightly less than the respective values of 4.73 and 9.30 kips given by Equations (17) and (18).

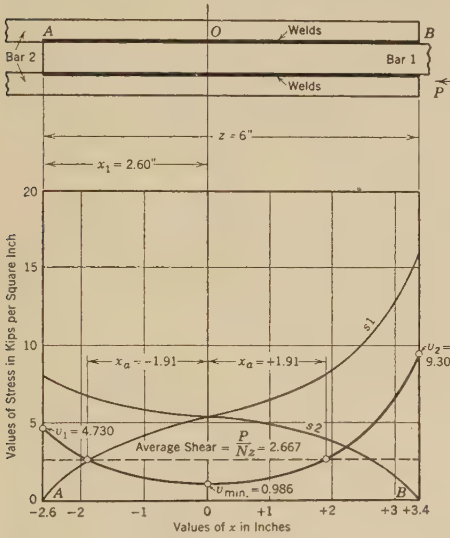

FIG. 2.—CROSS-SECTIONAL AREA OF BAR 2 TWICE THAT OF BAR 1.

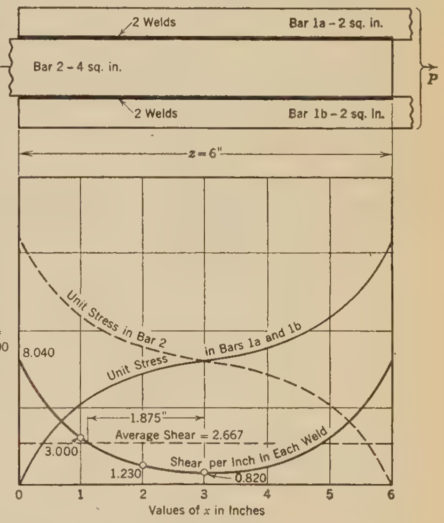

FIG. 3.—CROSS-SECTIONAL AREA OF CONNECTING BARS EQUAL.

Example 2.—Cross-Sectional Areas of Connecting Bars Equal.—Let $a_1 = a_2 = 4$ sq. in.; $z = 6$ in.; $N = 4$; $P = 64$ kips; $b = 1$; $\frac{z}{b} = 6$; $E = 30\,000$ kips per sq. in.; and $D = 15\,000$ kips per sq. in. Fig. 3 shows that, for this case, the end shear is practically equal to the limit of 8.0 kips derived by Equation (19).

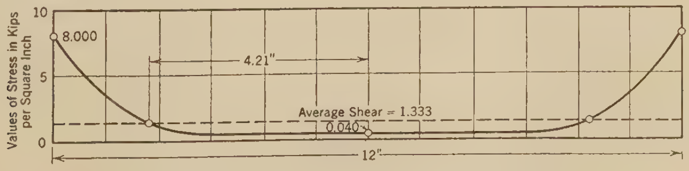

FIG. 4.—EFFECT OF INCREASING LENGTH OF WELD.

Example 3.—Effect of Increasing Length of Weld.—Let the data be the same as given in Example 2, except that $z = 12$ in. and $\frac{z}{b} = 12$. The result is shown by Fig. 4. The difference between v_1 and its limit has become negligible, and it is to be noted that the shear, for a considerable distance on each side of the center, is practically zero. This indicates (1) that the shorter the joint the more nearly uniform will be the distribution of the shear; and (2) that beyond a certain increase in the length of weld no appreciable reduction in the maximum shear will result from further increases in length.

ACKNOWLEDGMENTS

The writer wishes to acknowledge his indebtedness to O. E. Hovey, M. Am. Soc. C. E., and F. T. Llewellyn, M. Am. Soc. C. E., for many valuable suggestions.

DISCUSSION

F. T. LLEWELLYN,[2] M. AM. SOC. C. E. (by letter).—The Engineering Profession is greatly indebted to the author for this valuable contribution toward placing the actual behavior of certain forms of lap-joint on a rational basis. In its major features the analysis now presented is identical with a study which Mr. Troelsch showed to the writer in the summer of 1928, and of which blueprint copies were issued later under date of September, 1928. The writer believes that Mr. Troelsch's method of analysis applies to any form of joint, whether welded, riveted, or otherwise connected, in which the elements that transmit shear are disposed longitudinally. Comment will be given under the heads of mathematics, assumptions, detrusion ratio, and applications.

Mathematics.—Several curious relations, derivable from Mr. Troelsch's expressions, may be pointed out. Regardless of the relation between bar areas, in all cases the shear curve is symmetrical about the origin, although not necessarily of equal extent on both sides. When the area of Bar 1 (Fig. 1) is greater than that of Bar 2 the maximum shear will occur at the end of Bar 1.

Let z_1 be the distance from the origin to the farther end of the joint, and z_2, the distance to the nearer end. Then, for all ratios of bar area and for all values of z, the distance from the origin to the point of average shear lies between z_1 as a maximum, and $\frac{z_2}{\sqrt{3}}$ as a minimum, but never attains either limit.

Some expressions may be simplified by using functions of $\frac{z}{2\,b}$ instead of $\frac{z}{b}$. Thus, let v_1 be the shear at one end of the joint and v_2 the shear at the other end. Then,

$$v_1 + v_2 = \frac{P}{N\,b} \coth \frac{z}{2\,b} \quad \text{.......................} \quad (25)$$

Again, let v_m be the shear at mid-length of the joint; then,

$$v_m = \frac{P}{2\,N\,b} \operatorname{cosech} \frac{z}{2\,b} \quad \text{.......................} \quad (26)$$

In the special case when $a_1 = a_2$, all the author's expressions may be simplified, as follows:

Equation (15) becomes,

$$v = \frac{P}{2\,N\,b} \cosh \frac{x}{b} \operatorname{cosech} \frac{z}{2\,b} \quad \text{..................} \quad (27)$$

Equation (16) becomes,

$$v_{\text{min.}} = \frac{P}{2\,N\,b} \operatorname{cosech} \frac{z}{2\,b} \quad \text{.......................} \quad (28)$$

---

[2] Care, U. S. Steel Corporation, New York, N. Y.

Equations (17) and (18) become,

$$v_1 = v_2 = \frac{P}{2\,N\,b} \coth \frac{z}{2\,b} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(29)$$

and Equation (22) becomes,

$$\cosh \frac{x_a}{b} = \frac{2\,b}{z} \sinh \frac{z}{2\,b} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(30)$$

Assumptions.—The assumptions on which Mr. Troelsch's analysis is based might be acceptable ordinarily. In the present investigation, however, one of them must be qualified in order to represent correctly the actual behavior of joints. Another one must be investigated further if the analysis is to be of practical use.

The assumption that at any section the stress in each bar is distributed uniformly over that bar is not warranted either by the facts as to the bars or by the resulting effect on the welds. A method of determining the variable distribution and of translating it into an equivalent uniform distribution has been presented[3] by W. H. Weiskopf and Milton Male, Assoc. Members, Am. Soc. C. E. Without some such qualification the observed results of certain tests differ from the theoretical values by as much as 30 per cent.

The assumption that there is no tension or compression in the weld metal presumably refers to direct stress lengthwise of the joint. This assumption, although not rigorously correct, is acceptable for the reason that the effect of direct lengthwise stress is apparently negligible as compared with the deformation due to shear.

Mr. Troelsch avoids the necessity of analyzing the internal behavior of the welds by assuming the diagrammatic representation shown in his Fig. 1(*c*), wherein welds of rectangular form are depicted. The internal behavior of such prisms when subjected to shear on opposite sides is readily analyzed. Actually, the welds are of the triangular fillet form indicated in the section to the right hand of the author's Fig. 1(*b*). The internal behavior of a triangular prism subjected to shear on adjacent sides is evidently quite different. Mr. Troelsch makes no attempt to analyze the effect of different forms of weld. He requires that the value of the detrusion ratio, *D*, be determined experimentally for each material and for the cross-sectional dimensions of each form of uniting prism. The need of so doing militates against the predetermination of the manner in which a given joint may be expected to behave. This feature will be discussed in detail later.

Until recently, the assumption that all the elements of the joint deform in accordance with Hooke's law was considered a necessary precedent to analysis. In the discussion as to applications, that will be presented, it will be shown that actual behavior in practice can be reconciled with theory only by assuming that certain portions of the joint do not deform in accordance with Hooke's law. However, the writer is not in position to suggest a practical development of this alternative assumption.

---

[3] "Stress Distribution in Side-Welded Joints," by W. H. Weiskopf and Milton Male, Assoc. Members, Am. Soc. C. E., *Journal*, Am. Welding Soc., September and December, 1930.

Detrusion Ratio.—The determination and the proper application of the detrusion ratio, *D,* are essential preliminaries to the establishment of any relation between the theory and the results of tests. Evidently, the detrusion ratio is not the shearing modulus of elasticity of the material in question, but it is related to that modulus by some function of the shape and dimensions of the weld. Mr. Troelsch merely defines detrusion ratio as the measure of the stiffness of the weld. This is very true, but how shall its value be ascertained in practice? In a shearing test within proportional limits on a side-welded joint, if the distribution of stress were constant throughout the length of the weld, and if measurement could be made of the relative motion of the critical elements of the weld, its true detrusion ratio would be determinable by dividing the load (in pounds per square inch) by the amount of this relative motion or detrusion (in inches). The extent to which these conditions are attainable will now be discussed.

It is known by theory and confirmed by numerous tests, that the distribution of stress is not constant throughout the length of the weld. Its variation, however, can be averaged by plotting a sufficient number of observed deformations. As Mr. Troelsch points out, their mean value is the detrusion by which the average shear load is to be divided in order to determine the value of *D.* Thus, the actual condition of variable stress would cause no difficulty if the other condition could be met. Unfortunately, no practicable method has yet been suggested for measuring the relative motion of the critical elements of the weld. All the measurements thus far reported have had to be made between points outside the weld, and, therefore, the value of *D* derived therefrom denotes the stiffness of a zone made up of the weld plus strips of adjacent material rather than the stiffness of the weld itself. This value of *D* may be called the apparent detrusion ratio. No entirely satisfactory method of relating this ratio with the true detrusion ratio of the weld has yet been presented.

If it were physically possible to eliminate the need of establishing this relation by measuring the deformation of points on the weld itself, the question would still remain as to what points should be selected. In the case of a triangular fillet weld the only accessible points on the legs are at the ends of the hypotenuse. Presumably the deformation between these points would be greater than between any other points on the weld, and, therefore, it would not be an indication of the average behavior of the weld which is evidently the behavior contemplated in Mr. Troelsch's definition of *D.*

The most important feature that will pave the way toward the removal of these obstacles, and the reconciliation of the theory with all the observed test results, seems to be a rational analysis of the internal behavior of a triangular prism when subjected to shearing forces on its two adjacent legs, and the translation of this behavior into a quantity which, when multiplied by the known modulus of elasticity in shear, or possibly in tension, of the material, will give the true detrusion ratio, *D,* of the prism. One such analysis is tentatively offered in the paper by Messrs. Weiskopf and Male.[8] As far as the writer is aware, no criticism of this analysis has been presented and no substitute has been offered. A settlement of his feature would be of great value to those interested in the entire problem.

Applications.—All the previous comment has been predicated on the behavior of joints within the proportional limit, in line with one of Mr. Troelsch's fundamental assumptions. Numerous tests have now been made in which care was taken to keep within the elastic limit of the material. In many cases a beautiful correspondence between such tests and Mr. Troelsch's theory has been disclosed. It is proper to inquire what bearing the theory has on actual design, and also to what extent its conclusions are applicable under stresses beyond the elastic limit. The two questions are largely identical for the reason that practically all structures, although designed on the assumption of proportional deformation, involve local concentrations of stress that are far beyond the limits not only of proportionality, but also of elasticity. Engineers have adopted certain conventions which prevent such excess from becoming dangerous. In riveted work, they provide against dangerous concentration of stress on a portion of the rivet shank by restricting the minimum size of rivet that shall be used under specified conditions. It may be that similar legislation is required with respect to the cross-sectional sizes of fillet welds. One fact is quite apparent; namely, that the practical value of analysis such as that presented by Mr. Troelsch is qualitative rather than quantitative. The following example, which illustrates this fact, is interesting because it occurred, not in a laboratory, but in construction of considerable magnitude.

In 1930, during the construction of a new section of subway in New York City, the temporary roadway was carried on 27 and 30-in., rolled-steel girder beams which were spliced, end to end, not at the supports, but at overhanging points. The splices were made by means of side-welded joints. Computations based on Mr. Troelsch's theory indicate that the end shear was five times the average for which the joint was designed. An over-charge of dynamite caused stresses much beyond the contemplated load. If the welds had behaved proportionately they should have failed under their designed load, whereas they did not fail even under the added effect of the blast. The efficiency of the welds as a whole was doubtless due to their relief by a local straining of the ends beyond the elastic limit. This does not indicate any error in the theory. The example is merely one more illustration of the fact that actual construction involves conditions that are not assumed in any single theory.

A. S. Woodle, Jr.,[4] M. Am. Soc. C. E. (by letter).—The fundamental assumption on which this paper is based, is that the shearing deformation in the weld between the bars varies from a minimum at some point in the weld to a maximum at each end. The writer is unable to see the reason for this assumption.

It would seem that like most deformations, that of the bars in question would have a definite direction, and that this direction would be in the line of the stress in each bar. The two bars, therefore, deform in opposite directions from zero at one end of the weld to a maximum at the other end.

---

[4] Engr. of Plant, Baldwin Locomotive Works, Philadelphia, Pa.

The increase in unit deformation in each bar would follow a straight-line law, providing only that the bars and the weld between the bars are of uniform cross-section and uniform quality. The unit shear deformation in the weld at any point would be the sum of the unit deformations in the two bars at that point, which are necessarily in opposite directions.

As the locus of the sum of the ordinates of any two straight lines is a straight line also, it follows that the unit shear stress in the weld follows a straight-line law and, in the case of two bars of equal cross-section and the same material, would be a constant throughout the length of the weld.

MILTON MALE,[5] ASSOC. M. AM. SOC. C. E. (by letter).—The results of the analysis on welded joints as reported by Mr. Troelsch are paralleled in the companion paper by Mr. A. Hrennikoff on the distribution of stresses in riveted joints.[5a] The following comments are devoted to Mr. Troelsch's paper.

The "detrusion ratio," D, which is stated to vary with the nature of the weld, and the value of which is to be determined experimentally, may be derived theoretically[6] and its value shown to be a function of the shearing modulus. For the case of a 45° fillet the ratio is equal to $\frac{3}{4}\,G = 8\,700\,000$ lb. per sq. in. In any rational development of a theory of stress distribution in welded joints, the importance of a correct conception of the manner in which the weld acts under shearing deformation warrants further study and experimentation. Indeed, it forms the starting point on which the behavior of the joint as a whole can be predicated.

A graphical illustration of the behavior of fillet welds under the relatively simpler condition of loading—that of an end weld in shear[7]—indicates that the shearing stresses vary along the leg of the fillet by amounts ranging up to 450% of the stress in the bars. It is obvious that for purposes of design some constant intermediate value must be assumed which will approximate the results determined experimentally.

In the analysis by Mr. Troelsch, Equation (15) of the shear curve was derived by assuming that at any transverse section through the bars, the stress carried by those bars was distributed uniformly over their respective total cross-sectional areas, a_1 and a_2. This assumption is one that is commonly made, with a negligible degree of error, in connection with many features of design.

In the case of the welded joints under consideration, however, the error becomes important, because this assumption gives results that vary considerably from many specimens tested. Since Mr. Troelsch developed his equations, many similar equations have been derived independently, but in none but those of Weiskopf,[6] is the deformation in the bars taken into account.

[5a] See p. 437.

[6] "Stress Distribution in Side-Welded Joints," by W. H. Weiskopf and Milton Male, Assoc. Members, Am. Soc. C. E., *Journal*, Am. Welding Soc., September, 1930.

[7] "Calcul des Soudures prismatiques à Section Triangulaire," Streletsky and Nikolaieff, First Communications of the New International Assoc. for the Testing of Materials, Group D, 1930.

In this analysis, checked by many measurements made on specimens tested both at Massachusetts Institute of Technology, Cambridge, Mass., and at the University of Pittsburgh, Pittsburgh, Pa., the stresses in the bars are shown to be anything but uniform, and the parts next to the weld are shown to be stressed to a much greater degree than those farther away. Fig. 5 is an exaggerated representation of a side-welded joint under load, in which, Δ is the deformation of the joint bars, and q_0 and q_z are the deformations at the ends of the welds. In the particular case illustrated, the area of the joint bars exceeds the area of the grip bar; therefore, the maximum deformation, q_0, and maximum shear, v_0, occur at the end where the larger area terminates; that is, at the end of the joint bars. To assume that the shear distribution along the weld is the same for both uniform and non-uniform stress in the bars is not correct, and may lead to erroneous results.

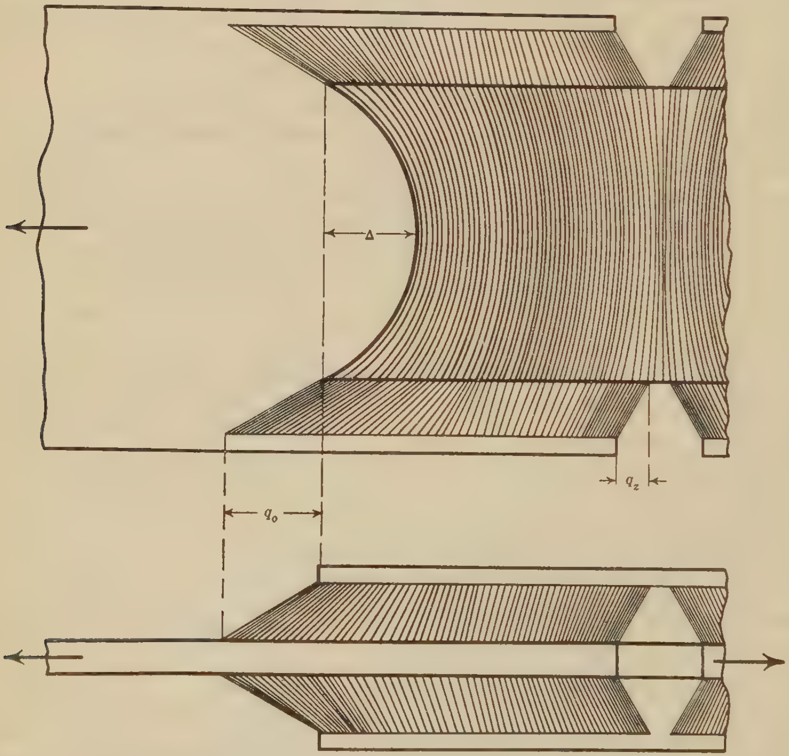

FIG. 5.—EXAGGERATED REPRESENTATION OF A SIDE-WELDED JOINT UNDER LOAD.

It has also been shown[6] that, depending on the ratio of the width of the bar between welds to the length of the weld, the percentage of the total cross-sectional area of the bars that is effective in transmitting stresses into the weld may have some value between 100 and 37, the percentage of effective area decreasing as the bars increase in width. Curves were plotted, which reduced the laborious computations necessary to determine these effective areas to simple slide-rule calculations.

The author's Examples 1, 2, and 3 indicate that in these specific cases the maximum shears are from three to six times the average shear. Since general design practice dictates the use of a safety factor of 4, it would follow necessarily that the welds should fail under loads far less than the working values, and they would so fail, provided these stress ratios are valid beyond the elastic range assumed in the analysis. The satisfactory behavior of welds when tested is evidence that the stresses tend to re-distribute themselves when the elastic limit is exceeded. In other words, the plastic deformation that the welds undergo by the time the ultimate load is reached, produces a shear curve more nearly approaching a horizontal straight line.

What then is the practical value of these analyses? To the writer's mind they serve as a basis for comparing different designs in order to determine which is the more efficient, the results being of a qualitative, rather than a quantitative, nature. As an example, a number of side-welded specimens tested by the Structural Steel Welding Committee of the American Welding Society were analyzed to determine what correspondence existed between their theoretical and actual behavior. The results are given in Table 1. It will be observed that although the correspondence between the computed theoretical behavior and the observed test results does not agree in magnitude, these results do show satisfactory correspondence in trend. It may be concluded, therefore, that although the theory does not enable the designer to predict what the actual ultimate strengths of two or more designs will be, it will permit him to determine in advance which of the two will be the more satisfactory in performance.

TABLE 1.—Comparison Between Theoretical and Actual Behavior of Side-Welded Specimens

William Hovgaard,[8] Esq. (by letter).—The analysis of shearing stresses in longitudinal fillet welds prescribed by the author for double butt-straps gives the same results as those reported by the writer in 1931.[9] The mode in which Mr. Troelsch's equations have been obtained and the form in which they appear, are different, but they are found to give the same results.

---

[8] Prof., Naval Constr., Mass. Inst. Tech., Cambridge, Mass.

[9] "The Stress Distribution in Welds"; "The Stress Distribution in Welded Overlapped Joints," *Proceedings*, National Academy of Science, November, 1930; see, also, "The Distribution of Stresses in Welded and Riveted Connections," *Proceedings*, National Academy of Science, June, 1931; and "A New Theory on the Distribution of Shearing Stresses, etc.", *Transactions*, Institution of Naval Architects, London, England, 1931.

The writer has made many experiments and much extended mathematical analysis in an attempt to obtain the physical constants, notably that called, *D,* in the paper, and also to determine the distribution of stresses in both plates.

The problem is of great importance in ships, where longitudinal girders are often attached in relatively short lengths to a continuous surface, such as a deck, subject to a longitudinal strain. The shearing stresses concentrated at the terminals of such girders have often given trouble, as, for instance, at the corners of deck-houses standing on a strength deck, or at the ends of short longitudinals fitted to the bottom plating of a ship. Whether such connections are riveted or welded, the general stress distribution will be the same; excessive stresses are likely to occur at the ends of the girders.

In Civil Engineering the same problem must occur in many cases, as, for instance, in cover-plates on the chords or flanges of girders. The double butt-strap selected for study by Mr. Troelsch is only an individual case among many.

CHARLES W. CHASSAING,[10] ASSOC. M. AM. SOC. C. E. (by letter).—The author has analyzed the shear in welded connections by means of a mathematical theory of elasticity. In so doing he has made some curious assumptions and has obtained some strange results.

For example, his assumption that at any section, *f-f,* the stress in each bar is distributed uniformly over that bar, and that there is no tension or compression in the weld metal, is in error. It leads to the conclusion that the stress in Bar 1 is not the same as that in Bar 2 at their points of contact. The stresses in each of the bars and in the weld metal must be the same at any point common to each.

In deriving his formulas the author has equated the tension strain to the shear strain. According to the mathematical theory of elasticity the cubical dilatation (that is, the change in volume per unit of volume of a small cube of elastic material in strain) is dependent on the tension and compression stresses entirely. The shearing stresses tend only to distort the cube, but not to change its volume.

The formulas give the greatest unit shear at the ends of the weld where it should be zero. It is impossible to have a shearing stress on the surface of any member that is not in contact with a surface. A shearing stress acting lengthwise with the weld must be accompanied by a shearing stress of equal intensity acting perpendicular to it.

According to the formulas the greatest shearing stress in the weld metal is not dependent on the length of the weld. It is unreasonable to suppose, that by increasing the length of the weld, the unit shearing stress would not be decreased.

The author's analysis does not take into account the dimensions of the weld in cross-section. According to his method, the area of the weld in contact with the bars does not enter into the final results.

---

[10] Structural Engr., Selden-Breck Constr. Co., St. Louis, Mo.

In the writer's opinion the problem can best be solved by assuming the weld members to act as a beam at the junction of the members with Bar 2. It is assumed that there is no shear stress on a longitudinal section, taken on the center line of Bar 2 as indicated by the dashed line in Fig. 6. Let Fig. 7 represent a half-section of the weld formed by a horizontal plane as shown. The couple, $\frac{P}{4}\left(\frac{t_1}{2} + t_2\right)$, must be balanced, in order to maintain equilibrium, by a couple, Fl. Consider the force, F, to be the resultants of tension and compression stresses distributed over the longitudinal section of Bar 2. It is scarcely necessary to mention that the other half of Bar 2 will balance these stresses.

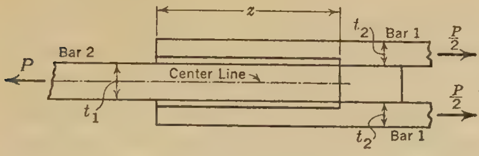

FIG. 6.

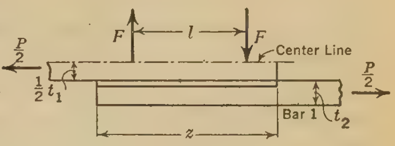

FIG. 7.

There is a moment, $\frac{Pt_1}{8}$, and a shear, $\frac{P}{4}$, acting on each member of the weld. Let w be the width of each member of the weld in contact with Bar 2; z, the length of the weld; and t_1 the thickness of Bar 1. The moment, $\frac{Pt_1}{8}$, and the shear, $\frac{P}{4}$, will have to be resisted by a beam of width, w, and depth, z. Let f_1 be the unit tension or compression stress at the ends of the weld; then,

$$f_1 = \frac{3}{4}\,\frac{Pt_1}{wz^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

The greatest unit shearing stress will occur at the center of the weld and will be one and one-half times the average unit shearing stress. The unit shearing stress at the ends of the weld will be zero. If V_1 is the unit shearing stress at the center of the weld,

$$V_1 = \frac{3}{8}\,\frac{P}{wz} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Referring to the author's Example 1, consider that Bar 2 is $1\frac{1}{4}$ in. by $6\frac{3}{8}$ in. and that $a_2 = 8.96$ sq in. Furthermore, for Bar 1 (1 in. by 4 in.) let $a_1 = 4$ sq in.; $t = 0.5$ in.; and $z = 6$ in. From Equation (31):

$$f_1 = \frac{3 \times 2 \times 64\,000}{4 \times 6^2} = 1\,333 \text{ lb per sq in.}$$

and, from Equation (32):

$$V_1 = \frac{3 \times 2 \times 64\,000}{8 \times 6} = 8\,000 \text{ lb per sq in.}$$

It seems that the tension stress as well as the shearing stress should be taken into account in designing a welded connection.

F. E. Fahy,[11] Assoc. M. Am. Soc. C. E. (by letter).—The author's solution of a rather complicated problem is interesting. It seems worth while, however, to point out that the assumption of a constant value for the detrusion ratio, *D,* will most likely hold only for short joints under low loads and that the assumption of a uniform distribution of tensile or compressive stresses throughout the cross-section of the connected bars will hold only near the centers of long joints, if at all. That the detrusion ratio, *D,* will vary in value throughout the length of the joint will be especially true if the bars are thin and, consequently, incapable of much deformation due to shearing forces acting in a longitudinal direction.

Consider two bars fastened together by a layer of glue, weld metal, or other cementing material, as shown in Fig. 8. Let the thickness of this layer of cementing material be called, *t,* and its shearing modulus of elasticity, E_s. The author's detrusion ratio then becomes equal to $\frac{E_s}{t}$. As *t* decreases, *D* increases, and when *t* is infinitesimally small, *D* approaches infinity; which means that unless there is a definite slipping or yielding of the cement, all the load, *P,* must be transferred from one bar to another within an infinitesimally small distance near one end of the joint. Since this is impossible there will be a plastic yielding of the cement at the ends of the joint and a corresponding adjustment in the distribution of the total shearing stress, *P,* throughout the joint (probably tending toward ultimate uniformity unless there is rupture in the meantime). This assumes, of course, that the bars are drawn up tightly against each other before welding, and neglects the bending effect of eccentricity.

The same argument holds for fillet welds. In Fig. 9 (in which *t* has been exaggerated for clearness), the capacity of the weld to deform, as shown by the dotted lines, *a-a,* depends almost entirely on the distance between the bars, assuming perfect fusion throughout. Under this same assumption of perfect fusion the capacity of the weld to deform, as shown by the dotted lines, *b-b,* depends on the capacity of Bar 1 to deform along those lines, which deformation in the case of a thin bar is quite small.

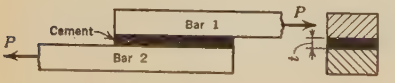

Fig. 8.

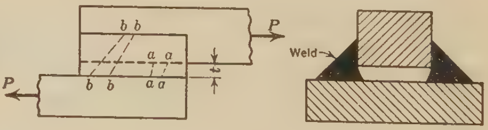

Fig. 9.

Even neglecting the foregoing considerations, however, it will be clear from the author's examples that the shearing stresses at the ends of the joint are beyond the range of elastic deformation of the weld metal. In his

---

[11] Asst. Prof., Civ. Eng., Antioch Coll., Yellow Springs, Ohio.

Example 2 the end shear of 8 040 lb per lin in. of weld is equivalent to 21 400 lb per sq in. at the base of a $\frac{3}{8}$-in. fillet, or 30 300 lb per sq in. of throat area; which means that plastic deformation of the weld metal will occur before the extreme values given by Equations (17) and (18) can be reached. A re-distribution of stress throughout the joint will result, with an ultimate distribution curve lying somewhere between the author's curve and the straight line of average shear.

The fact that the author's assumption of a uniform stress distribution throughout the cross-section of the bars is not entirely true, would tend to invalidate the foregoing comments to some extent, although by no means completely. There can be little doubt that even under low loads the high stress concentrations at the ends of the joint will cause plastic deformations that will result in lower stresses near the ends and higher stresses toward the center than the author's results show. This plastic flow near the ends of the joint means (perhaps fortunately) that the strength of a fairly ductile joint is not entirely limited by high shears at the ends.

A complete mathematical solution, which would take into account the deformations of the connected bars due to longitudinal shears, would be valuable; but it is perhaps impracticable. Photo-elastic tests on celluloid models, or a series of carefully made strain-gauge readings at a number of points along actual welded joints, would be of real value in pursuing, experimentally, the line of reasoning that the author has introduced.

W. H. JAMESON,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The formulas derived by the author when used in connection with the results obtained from actual tests reported in 1931 by the American Bureau of Welding[13] show rather surprising results. The author has proved mathematically that lengthening a weld beyond a very nominal length does not increase its strength. If tests proved this to be true, it would be disastrous for the welding industry and, for this reason, the writer feels that the fallacy in the author's assumptions should be shown. The writer has checked the derivation of all the formulas and, if the fundamental assumptions are accepted, has found the actual mathematical work to be correct. Therefore, the error must be in the assumptions since a true mathematical solution must check the results obtained from tests.

Mr. Troelsch states that the stress in Bar 1 (Fig. 1), is zero at A and increases to a maximum at B; and that, similarly, the stress in Bar 2 is zero at B and maximum at A. At some intermediate point, O, therefore, the unit stresses in the two bars will be equal, and the bars will have equal deformation. This assumption implies that the stress at any right section across either Bar 1 or Bar 2 is uniform throughout the bar. To the writer this seems unfounded. The bars are loaded eccentrically with forces along the weld at the edges and the probable deformation of the bars might be represented as shown in Fig. 10.[14]

[12] Designer, McClintic-Marshall Corporation, Bethlehem Steel Co., Bethlehem, Pa.

[13] Rept., Structural Steel Welding Committee, September, 1931.

[14] *Loc. cit.*, p. 100.

Fig. 1 (*e*) is the elevation of a section of the two bars, which shows actual slipping between the two bars at the weld. Actually, the bars cannot slip at the weld without tearing it so the value on which practically the entire solution is based, is incorrect. At the section, *O*, the stress in the two bars is the same only at the actual point of contact of the two bars and the weld.

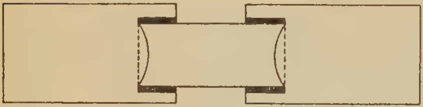

FIG. 10

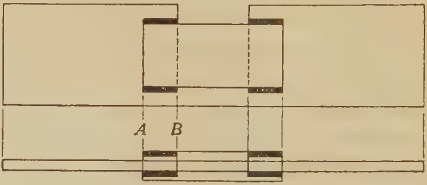

FIG. 11

At any other point on a right section at *O*, the stress is different from that at the point of contact defined herein.

A study of the results of tests given in the report referred to, shows that for a given size of weld, the ultimate stress on the throat of the weld, based on the total effective length[15] averaged about 38 000 lb per sq in. It is somewhat higher (up to 39 500 lb per sq in.) for short welds and somewhat lower (37 500 lb per sq in.) for long welds. This would tend to prove that probably the author's solution has some basis in fact, but since the difference is so small between long welds and short welds, it may be neglected for all practical purposes. For the same specimens, the maximum shear values by Equations (17) and (18) show wide divergence. The results of a few tests are given in Table 2 and all others tested by the writer using the author's formulas show similar results. All these tests were made on specimens with $\frac{3}{8}$-in. fillet welds made up as shown in Fig. 11. In Column (3), Table 2, the total ultimate strengths have been reduced to a common basis of a throat thickness of 0.265 in. before averaging. Columns (4), (5), and (6) show similar values for the average shear, and widely divergent values for the maximum shears by the author's formulas. Since it is unlikely that failure would occur at such different values as the author's formulas would indicate, the writer feels that for welds of ordinary length (certainly up to 12 in. and probably up to

[15] Rept., Structural Steel Welding Committee, September, 1931, p. 45.

at least 24 in.), it is perfectly safe to use the average shearing stress over the entire effective length of the weld. This is the method commonly used and there seems to be no reason to change it, or to fear that welded joints designed by this method will prove to be unsafe.

P. Wilhelm Werner,[16] Assoc. M. Am. Soc. C. E. (by letter).—A rather important problem is treated in this paper. The author has shown that the shear is concentrated near the ends of the weld. It may be of value to know whether there are any means by which a more even distribution of the shear, and thus a better utilization of the length of the weld, could be effected.

Consider the more general case represented by Fig. 12, showing diagrammatically a weld of the same type as that referred to by Mr. Troelsch, but in which the area of the connecting bars decreases uniformly from the full section to a fraction thereof at the ends of the weld. For the sake of simplicity in the following analysis it may be assumed that the two bars are equal, so that the full section is $a_1 = a_2 = a$, and that the area of the end sections is ka, in which, $k < 1$. The author's assumptions as regards the distribution of the direct stress in the bars, etc. (which may be considered to hold true for the type and relative sizes of the bars in question), have been adopted.

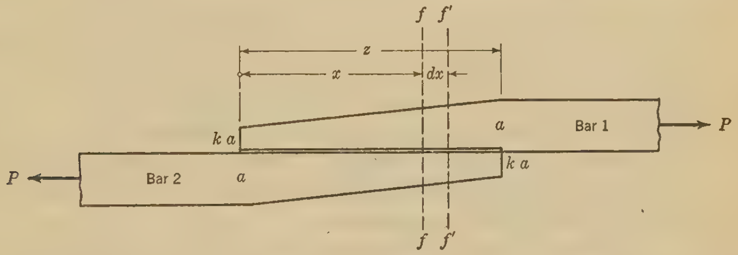

Fig. 12.—Diagrammatical Representation of Weld with Tapering Ends of Bars

The writer has found it more convenient to take the end of Bar 1 as the origin of co-ordinates. Otherwise, using the same nomenclature as the author, the equilibrium condition for that part of Bar 1 on one side of Section *f-f*, may be written, as follows:

$$s_2 = \frac{s_0 - s_1 \left[k + \frac{x}{z} (1 - k) \right]}{1 - \frac{x}{z} (1 - k)} \dots\dots\dots\dots\dots\dots\dots (33)$$

in which, $s_0 = \frac{P}{a}$.

From the equilibrium of horizontal forces on the element between Sections *f-f* and *f′-f′*:

$$v = \frac{a}{z\,N} \left\{ s_1 (1 - k) + \frac{ds_1}{dx} \left[z\,k + x (1 - k) \right] \right\} \dots\dots\dots (34)$$

---

[16] Civ. Engr., Stockholm, Sweden.

from which,

$$q = \frac{v}{D} = \frac{a}{z\,N\,D}\left\{s_1\,(1-k) + \frac{ds_1}{dx}\Big[z\,k + x\,(1-k)\Big]\right\} \ldots\ldots (35)$$

and by differentiating,

$$\frac{dq}{dx} = \frac{a}{z\,N\,D}\left\{\Big[zk + x\,(1-k)\Big]\frac{d^2 s_1}{dx^2} + 2\,(1-k)\,\frac{ds_1}{dx}\right\} \ldots\ldots (36)$$

According to the author's Equation (5), combined with Equation (33),

$$\frac{dq}{dx} = \frac{s_1 - s_2}{E} = \frac{z}{E}\,\frac{s_1\,(1+k) - s_0}{z - x\,(1-k)} \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Equating the values of $\frac{dq}{dx}$ in Equations (36) and (37), substituting $c = \frac{z^2\,N\,D}{a\,E}$, and reducing,

$$\frac{d^2 s_1}{dx^2} + \frac{2\,(1-k)}{z\,k + x\,(1-k)}\,\frac{ds_1}{dx} = \frac{c\,[s_1\,(1+k) - s_0]}{[z\,k + x\,(1-k)]\,[z - x\,(1-k)]} \ldots (38)$$

which corresponds to the author's Equation (7), with $a_1 = a_2 = a$.

As far as the writer knows, it is not possible to integrate Equation (38) directly. A numerical solution is obtained, however, by breaking up the equation into two simultaneous differential equations of the first order. This will be illustrated by the following examples.

Example 1.—Letting $k = \frac{1}{2}$, and assuming the same numerical values as in the author's Example 2, $c = \frac{6^2 \times 4 \times 15\,000}{4 \times 30\,000} = 18$ in., and $s_0 = \frac{64}{4} = 16$ kips per sq in. After reducing, Equation (38) becomes,

$$\frac{d^2 s_1}{dx^2} + \frac{2}{6+x}\,\frac{ds_1}{dx} = \frac{108\left(s_1 - \frac{2}{3}\,s_0\right)}{(6+x)\,(12-x)} \ldots\ldots\ldots\ldots\ldots (39)$$

In Equation (39), substituting $\frac{ds_1}{dx} = w$ and $\frac{d^2 s_1}{dx^2} = \frac{dw}{dx}$:

$$\frac{dw}{dx} = \frac{108\left(s_1 - \frac{2}{3}\,s_0\right)}{(6+x)\,(12-x)} - \frac{2\,w}{6+x} \ldots\ldots\ldots\ldots\ldots (40a)$$

and,

$$\frac{ds_1}{dx} = w \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40b)$$

Equations (40*a*) and (40*b*) are two simultaneous differential equations of the first order, which can be solved by the numerical integration method developed by Runge.[17] To save space, the somewhat elaborate numerical calculations will be omitted here, and only the result will be given. It may be mentioned that the values of both s_1 and $w = \frac{ds_1}{dx}$ are obtained simultaneously in the same integrating operation. The values of s_2 and v are then calculated according to Equations (33) and (34), respectively, with $k = \frac{1}{2}$.

---

[17] "Ueber die numerische Auflösung von Differentialgleichungen", von C. Runge, *Mathematischen Annalen*, Bd. 46 (1895), or "Leitfaden sum graphischen Rechnen", von R. Mehmke, Leipzig, 1917.

The result is shown graphically in Fig. 13. It is seen that the maximum shear at the ends of the weld has decreased only a comparatively moderate amount, namely, from 8.04 to about 7.5 kips per sq in.

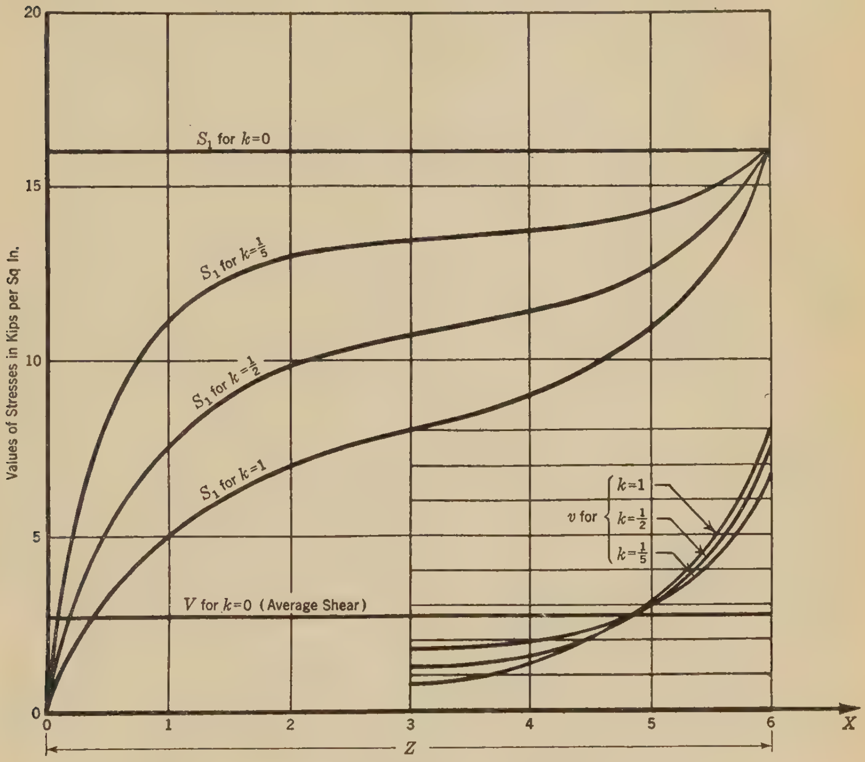

FIG. 13.—STRESSES IN WELD WITH TAPERING ENDS OF BARS

As the shear is symmetrical about the center line of the weld, it has been plotted for only one-half the length of the weld. The unit stress, s_2, is identical to s_1, but reversed, and, therefore, has not been given in Fig. 13.

Example 2.—Let $k = \frac{1}{5}$, and the other values as given previously. Equation (38) then becomes:

$$\frac{d^2 s_1}{dx^2} + \frac{4}{3 + 2x}\,\frac{ds_1}{dx} = \frac{135\left(s_1 - \frac{5}{6}\,s_0\right)}{(3 + 2x)\,(15 - 2x)} \quad\ldots\ldots\ldots\ldots(41)$$

from which,

$$\frac{dw}{dx} = \frac{135\left(s_1 - \frac{5}{6}\,s_0\right)}{(3 + 2x)\,(15 - 2x)} - \frac{4\,w}{3 + 2x} \quad \ldots\ldots\ldots\ldots\ldots (42a)$$

and,

$$\frac{ds_1}{dx} = w \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42b)$$

The integrals of Equations (42*a*) and (42*b*) are obtained in the same manner as for Equations (40*a*) and (40*b*). The values of s_2 and v are then calculated according to Equations (33) and (34), respectively, with $k = \frac{1}{5}$.

This result is shown also graphically in Fig. 13. It is seen that in this case the maximum shear at the ends of the weld has further decreased, that is, to about 6.5 kips per sq in. This decrease is considerable when compared with the average shear, which is $v = 2.667$ kips per sq in.

For comparison, the values of s_1, s_2, and v from the author's case, Example 2, have also been plotted in Fig. 13. It appears that the more the bars are tapered, the more evenly will the shearing stresses be distributed over the length of the weld. If the ends of the bars were wedge-shaped ($k = 0$), the shear would be constant throughout the length of the weld, and would be equal to the average shear. The unit stresses in the bars would then likewise be constant throughout the length of the weld, and would be equal to s_0.

Even a short taper of the very ends of the bars, reaching over only part of the weld, would be likely to effect a considerable decrease of the shear at the ends of the weld. A reduction of the shearing stresses in these places is desirable not only because it effects a more favorable distribution of the stresses, but possibly also because a concentration of the stresses at points of discontinuation, such as those constituted by the ends of the weld, may encourage the beginning of failure. As far as the writer is aware, a taper reaching at least over part of the weld at the very ends of the bars should not generally meet with any practical difficulties.

ISAMU OHNO,[18] ESQ. (by letter).—In connection with the paper by Mr. Troelsch the writer wishes to call attention to the application of the method to a plate to which a shorter reinforcing plate has been welded. Let Fig. 14 be a representative part of such a reinforced plate, for which the center of co-ordinates is at Point O (Fig. 14(*b*)). Since the reinforcing plate is sym-

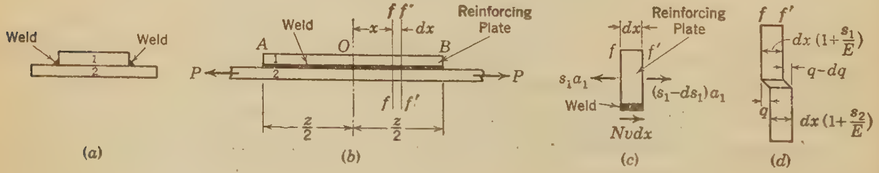

FIG. 14

---

[18] Tokushima, Japan.

metrical, only the right half, $O\,B$, need be considered. Using the author's notation and logic, his formulas, Equations (2), (8), (9), and (10) are derived as in the original paper.

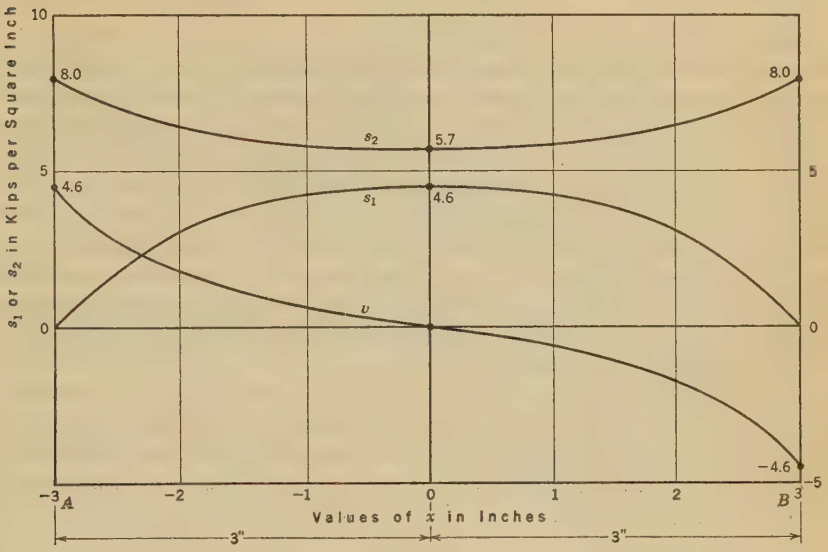

FIG. 15

In the present case, however, the boundary conditions are different; so that $v = 0$ when $x = 0$, and $s_1 = 0$ when $x = \frac{z}{2}$. Therefore, $K_1 = 0$ and

$$K_2 = \frac{P}{\cosh \frac{z}{2\,b}\,(a_1 + a_2)}.$$

Substituting these values in the author's formulas his Equations (23), (24), and (15) may be rewritten, as follows:

$$s_1 = \frac{P}{a_1 + a_2}\left[1 - \frac{\cosh \frac{x}{b}}{\cosh \frac{z}{2\,b}}\right] \quad \text{.....................(43)}$$

$$s_2 = \frac{P}{a_1 + a_2}\left[1 + \frac{a_1 \cosh \frac{x}{b}}{a_2 \cosh \frac{z}{2\,b}}\right] \quad \text{...............(44)}$$

and,

$$v = -\frac{P\,b\,D \sinh \frac{x}{b}}{a_2\,E \cosh \frac{z}{2\,b}} \quad \text{......................(45)}$$

If the area, a_1, of the reinforcing plate is 4 sq in., the area, a_2, of the main plate is 8 sq in., and if the other quantities are the same as in the author's Example 1, the resulting shears and tensile stresses will be as shown in Fig. 15.

HENRY W. TROELSCH,[19] M. AM. SOC. C. E. (by letter).—In preparing the analysis presented in this paper, the writer purposely made the underlying assumptions as simple as possible. Any other procedure would have involved complicated mathematical expressions, which would have tended to obscure the results. However, for stresses within the elastic limit, the theory offers a picture of the distribution of shear in longitudinal fillet welds which is qualitatively correct. Whether it can be made to yield numerically correct values of the shear in various parts of the welds can be determined only by checking against the results of tests. Such tests as have come to the writer's attention indicate that the distribution of shear can be closely represented by Equation (15), provided the proper values of the detrusion ratio, D, and the areas, a_1 and a_2, are used.

The closeness of the correspondence between test and theory is shown in Fig. 16, plotted from the results of two tests selected from those made by the late J. Hammond Smith, M. Am. Soc. C. E., at the University of Pittsburgh, Pittsburgh, Pa.[20] The plotted points show the measured slip between gauge points on the bars. In Fig. 16(b) the curve is plotted from the equation,

$$q = \frac{v}{D} = \frac{Pb}{a_2\,E}\;\frac{\cosh \dfrac{x}{b}}{\sinh \dfrac{x_1}{b}}$$

using for a_1 and a_2 the actual area of the bars, and for D the value, 7 100 000, which is required to make the curve fit the plotted points.

In Fig. 16 (a), the plates are wider, and the effect of the non-uniform distribution of their tension, to which Mr. Llewellyn and Mr. Male have referred, becomes evident. To make the formula agree with the test results it is necessary to reduce the values of a_1 and a_2 from the actual area, 3.0, to 1.59 for a_1 and 2.44 for a_2. The detrusion ratio, D, is 5 480 000. The amount of reduction in the areas of the plates is less than that obtained by Messrs. Weiskopf and Male.[3] It is to be noted, however, that the results agree with the findings of Messrs. Weiskopf and Male to the extent that the reduction for Bar 1 is greater than that for Bar 2.

The detrusion ratio obtained from these tests is not that for the welds alone, but for the welds plus adjacent parts of the bars. For purposes of analysis it is impossible to say where the weld stops and the plate begins. It may be that an analysis, which, like the foregoing, is based on "equivalent areas" and a slip between points near the welds, is as near a practical solution as can be expected.

---

[19] Designing Engr., Am. Bridge Co., New York, N. Y.

[20] "Stress-Strain Characteristics of Welded Joints," by J. Hammond Smith, *Journal*, Am. Welding Soc., September, 1929, p. 79.

The fact that the theory, with such modifications as have been suggested, shows close agreement with measured deformations, indicates that it is substantially correct. The theories suggested by Mr. Woodle and Professor Chassaing, based on a different set of fundamental assumptions, show no such agreement with the tests.

FIG. 16.

It is to be observed that in both these tests the unit shears for which the deformations were measured, are such as would be applied to similar welds in designing practice. The average shear in the welds is 2 670 lb per lin in. of $\frac{5}{16}$-in. fillet weld.

It is undoubtedly true, as Mr. Llewellyn and Mr. Male have pointed out, that welded joints will carry, without failure, loads which according to this theory would stress the ends of the welds beyond the breaking point. This can be explained by assuming that after a weld has been stressed to the yield point, further deformation occurs without much increase in stress, so that for a considerable distance near each end of the joint the welds are stressed to the yield point or slightly beyond it. A joint in such a state of stress will probably carry its load satisfactorily if the load is constant. On the other hand, as has been pointed out[21] by H. M. Priest, M. Am. Soc. C. E., impact or variable loads, and especially loads which alternate between tension and compression, might lead to a fatigue failure because of repeated over-stressing of the ends of the welds. Inasmuch as variable and alternating stresses occur regularly in bridge trusses, an experimental investigation of the behavior of welded joints under the action of such stresses should yield valuable information.

---

[21] "The Practical Design of Welded Steel Structures," by H. M. Priest, *Journal*, Am. Welding Soc., August, 1933.

Mr. Werner's analysis of a joint with tapered bars indicates that to obtain anything approaching a uniform distribution of shear, the bars must be tapered nearly to a knife-edge; that is, k must be nearly zero; for in Mr. Werner's Example 2, with k as small as one-fifth, the end shear is still 2.5 times the average shear. The fact that a taper tends to eliminate excessive local stresses at an abrupt change in section has long been recognized in the practice of finishing re-entrant angles of machined parts with a fillet.

Mr. Ohno's application of the theory to a reinforcing plate is along the line suggested by Professor Hovgaard in connection with longitudinal girders or deck-houses welded to the deck of a ship. It should be possible to make a similar application to the cover-plates of a plate girder, although the mathematical analysis will be complicated by the variation of the flange stress along the length of the girder.

WORK OF RIVETS IN RIVETED JOINTS

By A. Hrennikoff,[1] Esq.

With Discussion by Messrs. Henry W. Troelsch, Henry B. Seaman, A. H. Finlay, F. P. Shearwood, W. P. Roop, H. N. Hill and Marshall Holt, Donald E. Larson, A. E. R. de Jonge, and A. Hrennikoff.

Synopsis

An investigation of how a force acting on a joint, made up of plates, divides itself among the rivets, is the subject of this paper. Part I is a qualitative study, with some observations on conventional design methods. This is followed, in Part II, by the derivation of formulas for the forces developed by the rivets in a few simple types of joints, based on the assumption that a rivet develops a force proportional to deformation. In Part III the formulas in Part II are applied to the determination of the numerical values of the forces of the rivets, based on the value of the coefficients found analytically.

PART I.—Conventional Design and Actual Work of Riveted Joints

Despite their widespread use in engineering, riveted joints and the actual work in such joints when stressed, are not well understood. A rigid theoretical investigation of this subject is difficult and, in many respects, indefinite. It requires certain assumptions to start with, which may be not quite true for all cases. For example, conditions under which a rivet has been driven would affect its work considerably. A badly driven field rivet would act quite differently from a good shop rivet.

One difficulty is that inelastic deformations begin to take place a considerable time before the limit of safety is reached. Furthermore, formulas that could be developed along more or less rational lines would be difficult to use in actual practice, except in plate work (boilers, tanks, etc.). Nevertheless, the writer attempts to present herein an analysis which, while admittedly not perfect, may raise some questions of interest for discussion.

Note.—Published in November, 1932, *Proceedings*.

[1] Instr., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

"Standard practice" has developed several arbitrary methods of design that remain in vogue mostly because they are convenient. Consider the simple case of a lap-joint (Fig. 1) with two plates in tension, connected by several rows of rivets equally spaced. Imagine the joint to be divided longitudinally into equal strips with one row of rivets in each, and consider one strip as representative of the work done by the entire joint.

Let $w =$ the width of the strip; t, the thickness of each plate; d, the diameter of the rivet; p, the pitch of rivets; n, the number of rivets in each longitudinal strip; and F, the total pull on one strip.

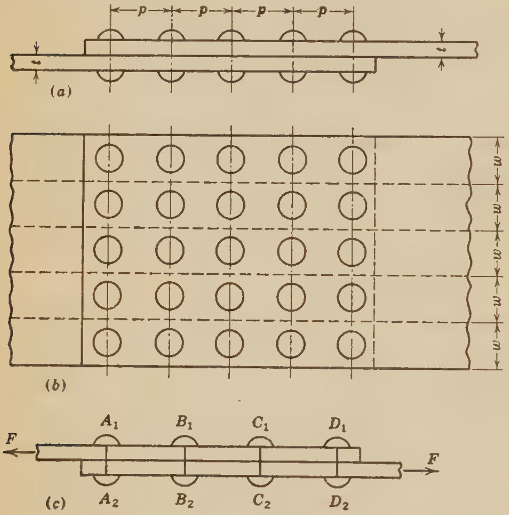

FIG. 1.

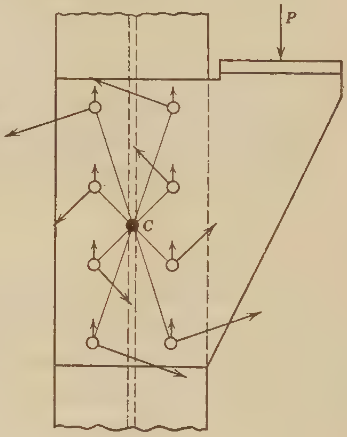

FIG. 2.

It is customary to assume that the force, F, acting on a joint, is divided equally among the rivets, so that each rivet is stressed by the force, $\frac{F}{n}$, in shear and in crushing. The unit stresses are expressed by the following equations:

For shear,

$$s_s = \frac{F}{n \frac{\pi d^2}{4}} = \frac{4F}{\pi d^2 n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

For crushing,

$$s_c = \frac{F}{t d n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Assuming certain safe unit stresses in shear and crushing, s_s and s_c, the number of rivets required to transmit the force, F, safely must be not less than that computed by either of the following equations:

$$n_s = \frac{4F}{\pi s_s d^2} = k_s \frac{F}{d^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and,

$$n_c = \frac{F}{s_c\, t\, d} = k_c \frac{F}{t\, d} \quad \text{.......................(4)}$$

in which, k_s and k_c, depending on s_s and s_c, are established by experiment.

It must be pointed out that a rivet cannot work in shear and bearing without deforming; therefore, the standard accepted theory is based on the assumption that a rivet is deformed even when it is under a small stress. Although this may be true in the case of imperfect rivets, a perfect one does not deform until the friction force between the plates, caused by tension in the shank, is exceeded.

Sometimes engineers state that a rivet is good only as long as it does not deform at all and that it should be designed on the basis of friction only. A safe force for one rivet on this basis would be also proportional to the cross-sectional area of the rivet, thus:

$$F_1 = cd^2 \quad \text{.........................(5)}$$

in which, c is a coefficient, depending on the coefficient of friction between the plates, temperature, and other conditions of driving the rivet, Young's modulus, and the coefficient of expansion of the metal For the total number of rivets in a row this would give an expression similar to Equation (3) in the design for shear, namely,

$$n_f = k_f \frac{F}{d^2} \quad \text{.........................(6)}$$

in which, k_f again would be established by experiment.

It must not be concluded, however, that design for shear is the same as that for friction. This simple method of designing on the basis of friction seems to be quite correct in the case of only one rivet in a longitudinal row, or two rivets in case of plates of equal thicknesses. For more than two rivets in a row the method breaks down, as may be seen if deformation of the plates is taken into account.

Let Fig. 1(c) represent a lap-joint of the type shown in Fig. 1(a) with four rivets in a row. If the rivets are working in friction only the plates must not slip with respect to each other under the action of Force F; that is, the lengths, $A_1 B_1$, of the upper plate, and $A_2 B_2$, of the lower plate, which are equal before the force begins to act, must remain so during the action of force. In other words, the elongation of the section, $A_1 B_1$, in the upper plate under the force, F, must equal that of the corresponding section, $A_2 B_2$, in the lower plate. That means that the tensile forces in each plate must be equal (the plates being of the same thickness, width, and metal), which can happen only if Rivet A has transmitted to the lower plate one-half the force, F, that made the tensile forces equal in both plates in the section, A-B.

If a larger or a smaller force is transmitted by the rivet, A, the plates do not stretch equally, they slip, and at least one of the rivets deforms. Similarly, if the rivet, C, does not deform, the parts, B-C, of the upper and lower plates must stretch equally, which is possible only if the rivet, B, does no work. The same reasoning would show that Rivet C does no work either and that Rivet D transmits the other half of the force, F; that is, if the rivets work in friction only, it is really the outer rivets, one on each side of the joint, that actually work, the intermediate rivets performing no work. Hence, it follows that a method of design based on allowing a uniform value for each rivet, working in friction, is wrong.

What probably happens in the row of rivets, when the strip (Fig. 1), is subjected to a gradually increasing force, F, is that when F is small, only the outer rivets, A and D, do any work, each transmitting by friction a force, $\frac{F}{2}$. As soon as the increasing tensile force, F, equals the maximum friction force that can be developed by two rivets, the outer rivets begin to deform as the plates slip at the points, A and D.

Then the length, $A_1 B_1$, is greater than $A_2 B_2$, since $A_1 B_1$ is elongated by the greater force. This brings the rivet, B, into play in such a way that it takes up the remainder left by the rivet, A; that is $X_B = \frac{F}{2} - X_A$, in which, X_A and X_B are the forces developed by the rivets, A and B.

Force X_B is developed entirely by friction, and X_A is the sum of the forces developed by friction and shear, and crushing ($X_A = X_{Af} + X_{As}$). The force, X_{Af}, developed by friction at Rivet A probably remains more or less constant, as the tensile force continues to increase, and it is equal or (more likely) somewhat less than the maximum friction force that a rivet can develop before it begins to deform.

It is reasonable to assume that the other part, X_{As}, of the total force, X_A, developed by the rivet (that due to shear), is proportional to the slip of plates at Point A.

In the foregoing example, Rivet C works the same as Rivet B, and Rivet D works the same as Rivet A. As the tensile force, F, increases still more both X_A and X_B increase; at a certain time, the rivet, B, cannot develop its share by friction alone and it also begins to deform. The force, X_B, taken by Rivet B after that is the sum of the forces developed by friction and shear, and crushing ($X_B = X_{Bf} + X_{Bs}$). The force developed by friction, X_{Bf}, is the same as that of Rivet A. When X_B increases, the friction force, X_{Bf}, remains constant and the force developed by shear and crushing, X_{Bs}, increases in proportion to the deformation.

If the friction force, X_{Af}, and the coefficient of proportionality between the shearing force developed by a rivet and its deformation are determined by experiment, a reasonably rigid theory of a riveted joint may be deduced by means of a mathematical analysis.

PART II.—FORMULAS FOR THE FORCES ACTING ON RIVETS

Following the logic of Part I, it is evident that the value of X_{Af} may vary widely for the same size of rivet, depending on how well the rivet has been driven. For a bad rivet it may approach zero. In that case, the rivet works only in shear and crushing and develops a force proportional to deformation. Formulas developed under this assumption will evidently be on the safe side. The assumption is in agreement with general practice in the design of riveted joints that transmit bending moments, as in the case of a joint in the web of a plate girder, or a bracket connection to a column (Fig. 2).

The usual procedure in these cases is to find the center of gravity of the rivets (Point *C*, Fig. 2) and to allow for each rivet a force, proportional to the distance from the center of gravity, and at right angles to the line from the center of gravity to the rivet. Equating the sum of the moments of all the rivets to the external moment, the force due to bending can be found for each rivet.

This procedure is really based on two assumptions: First, that the ends of the connected parts, considering bending moment only, turn with respect to each other about the center of the rivets, due to which fact the rivets become deformed proportionally to their distances from the center of gravity of rivets; and, second, that the forces of the rivets are proportional to their deformations.

This second assumption will be adopted in the following examples for the case of a lap-joint (or butt-joint) of plates in direct tension or compression.

Examples

Example 1.—Lap-Joint with Three Rivets.—Let Fig. 3 represent a longitudinal strip of a lap-joint similar to Fig. 1(*c*), held by three rivets, *A*, *B*, and *C*. It is evident from symmetry that Rivet *A* develops the same force, *X*, as Rivet *C*; then the middle rivet, *B*, takes the remainder, or $F - 2X_1$.

FIG. 4.

In the upper plate a tensile force, $F - X_1$, acts between the rivets, *A* and *B*, and a force, X_1, acts between the rivets, *B* and *C*. In the lower plate a tensile force, X_1, acts between A_2 and B_2 and the force, $F - X_1$, acts between B_2 and C_2.

Under these tensile forces the plates elongate. The portions, $A_1 B_1$, and $B_2 C_2$, each stretch an amount equal to $\frac{F - X_1}{w\,t\,E}\,p$, and the portions, $B_1 C_1$ and $A_2 B_2$, stretch an amount equal to $\frac{X_1}{w\,t\,E}\,p$; or, in other words, the points, A_1 and B_1, move leftward from Point C_1, and the points, B_2 and C_2, move rightward relative to Point A_2.

Curves of displacements of different points on the plates with respect to Point C_1 on the upper plate and Point A_2 on the lower plate, are shown in Fig. 3. The ordinates represent the relative movements of points on the plates having corresponding abscissas, referred to C_1 or A_2; thus, $N\,Q = W\,T = \frac{X_1}{w\,t\,E}\,p$; and, $M\,K = L\,U = \frac{F - X_1}{w\,t\,E}\,p$. Having represented on Fig. 3 the relative displacements of points on the same plate, it is required to find how much Point A_1 will move with respect to Point A_2, B_1 with respect to B_2, and C_1 with respect to C_2.

Imagine that one point of the joint, C_1, is fixed in space. This is quite legitimate since it is the relative displacements of the points of the joint that matter. Then, Points A_1 and B_1 move, as has been seen, to the left from their original positions the distances, $\frac{F}{w t E}\,p$ and $\frac{X_1}{w t E}\,p$, respectively. Points A_2, B_2, and C_2 also move in some manner, a distance as yet undetermined.

If the point, A_2, were fixed, the displacements of B_2 and C_2 would be, respectively, $\frac{X_1}{w t E}\,p$ and $\frac{F}{w t E}\,p$ to the right. Then, the relative displacement of A_1 with respect to A_2 would be $\frac{F}{w t E}\,p$ to the left; the movement of B_1 with respect to B_2 would be $\frac{2\,X_1}{w t E}\,p$ to the left; and the movement of C_1 relative to C_2 would be $\frac{F}{w t E}\,p$ to the left. Point A_2 is not fixed, however; it moves in space in the direction of the force (to the left) an unknown distance, l. Therefore, the displacements are actually: A_1 relative to A_2, to the left, $\left(\frac{F\,p}{w t E} - l\right)$; B_1 relative to B_2, to the left, $\left(\frac{2\,X_1\,p}{w\,t\,E} - l\right)$; and C_1 relative to C_2, to the left, $\left(\frac{F\,p}{w t E} - l\right)$. (Perhaps it would be better to state, "C_2 relative to C_1, to the right" since the assumption has been made that Point C_1 was fixed; however, the two statements are mathematically equivalent.)

The relative displacements, $(A_1\text{-}A_2)$, $(B_1\text{-}B_2)$, and $(C_1\text{-}C_2)$, are measures of the deformations of the rivets, and must be of such magnitudes, as to bring into play the forces distributed among them; namely, X_1 for Rivets A and C, and $(F - 2X_1)$ for Rivet B. Assumed proportionality between the deformation and the force of the rivet gives the necessary equations with the unknowns, l and X_1, as follows,

$$\left(\frac{F}{wtE}\,p - l\right) = k\,X_1 \quad \text{.....................(7)}$$

and,

$$\left(\frac{2\,X_1}{wtE}\,p - l\right) = k\,(F - 2\,X_1) \quad \text{..................(8)}$$

The coefficient of rivets, k, is assumed to be known.

In Fig. 3, if the distance between the lines, 1-1 and 2-2, is $-l$, the deformation of any rivet is equal to the vertical ordinate between the curves, $M\,N\,O$ and $S\,T\,U$, taken under that rivet. This holds true for the case of a lap-joint or a butt-joint with any number of rivets.

From Equations (7) and (8), the force acting on Rivets A and C is,

$$X_1 = \frac{w\,t\,E\,k + p}{3\,w\,t\,E\,k + 2\,p}\,F = C_1 F \quad \text{..................(9)}$$

and the force acting on Rivet B is,

$$X_2 = \frac{w\,t\,E\,k}{3\,w\,t\,E\,k + 2\,p}\,F = C_2 F \quad \text{.................(10)}$$

in which, the coefficients of F, marked C_1 and C_2, represent the fractions of the total force, F, taken up by each rivet in question. When the rivets are very stiff, k is small and approaches zero as a limit; then, $X_1 = \frac{F}{2}$ and $X_2 = 0$. On the other hand, when the rivets are very weak, k is large and approaches infinity as a limit. Then, $X_1 = \frac{F}{3}$ and $X_2 = \frac{F}{3}$; that is, when the rivets are stiff and the plates weak a relatively smaller part of the total force, F, is transmitted by the middle rivet.

If similar lap-joints with four, five, and six rivets, are analyzed, the following expressions are derived for the force acting on rivets:

Lap-Joint with Four Rivets:

Outer rivet,

$$X_1 = \frac{wtEk + 2\,p}{4\,wtEk + 4\,p}\,F = C'_1 F \quad \text{..................(11)}$$

Inner rivet,

$$X_2 = \frac{wtEk}{4\,wtEk + 4\,p}\,F = C'_2 F \quad \text{..................(12)}$$

Lap-Joint with Five Rivets:

Outer rivet,

$$X_1 = \frac{2\,p^2 + 4\,pwtEk + (wtEk)^2}{4\,p^2 + 10\,pwtEk + 5\,(wtEk)^2}\,F = C''_1 F \;\ldots\ldots\ldots (13)$$

Second rivet,

$$X_2 = \frac{pwtEk + (wtEk)^2}{4\,p^2 + 10\,pwtEk + 5\,(wtEk)^2}\,F = C''_2 F \;\ldots\ldots\ldots (14)$$

Middle rivet,

$$X_3 = \frac{(wtEk)^2}{4\,p^2 + 10\,pwtEk + 5\,(wtEk)^2}\,F = C''_3 F \ldots\ldots\ldots (15)$$

Lap-Joint with Six Rivets:

Outer rivet,

$$X_1 = \frac{4\,p^2 + 6\,pwtEk + (wtEk)^2}{8\,p^2 + 16\,pwtEk + 6\,(wtEk)^2}\,F = C'''_1 F \ldots\ldots\ldots (16)$$

Second rivet,

$$X_2 = \frac{2\,pwtEk + (wtEk)^2}{8\,p^2 + 16\,pwtEk + 6\,(wtEk)^2}\,F = C'''_2 F \;\ldots\ldots\ldots (17)$$

Third rivet,

$$X_3 = \frac{(wtEk)^2}{8\,p^2 + 16\,pwtEk + 6\,(wtEk)^2}\,F = C'''_3 F \;\ldots\ldots\ldots (18)$$

A discussion similar to that given for the case of three rivets leads to the conclusion—in the cases of four, five, and six rivets—that for very stiff rivets and weak plates the inner rivets take only a small portion of the total force, but when the plates are strong and the rivets weak, the distribution of forces between rivets in a joint approaches equality.

Example 2.—Butt-Joint with Two Splice Plates and Four Rivets Symmetrical About the Butt-Joint.—Assume that the splice plates in Fig. 4 are of equal thickness, t_2, and different from the thickness, t_1, of the main plate. Let Rivet A transmit to each splice plate the force X_1; and let Rivet B transmit to each splice plate the force, $X_2 = \frac{F}{2} - X_1$. The force exerted by each rivet may be expressed as follows,

$$\frac{F - 2\,X_1}{w\,t_1\,E}\,p - l = k\,X_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

and,

$$\frac{X_1 p}{wt_2 E} - l = k\left(\frac{F}{2} - X_1\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

from which,

$$X_1 = \frac{2\,t_2 p + wt_1 t_2 Ek}{(4\,t_2 + 2\,t_1)\,p + 4\,wt_1 t_2 Ek}\,F = C_1'''' F \ldots\ldots\ldots\ldots (21)$$

and,

$$X_2 = \frac{t_1 p + w t_1 t_2 E k}{(4\,t_2 + 2\,t_1)\,p + 4\,w t_1 t_2 E k}\,F = C_2'''' F \ldots\ldots\ldots\ldots(22)$$

From these equations it follows that if $t_1 = 2\,t_2$, the force is divided equally among the rivets. If $t_1 \neq 2\,t_2$, the rivet on the side of the greater thickness works less.

Example 3.—Case of Butt-Joint with Two Cover-Plates and Six Rivets, Symmetrical About the Butt-Joint.—Following the same logic as in Example 2, the forces transmitted by rivets to each cover-plate are:

$$X_1 = \tfrac{1}{2}\,\frac{2\,p^2 t_2\,(t_1 + 2\,t_2) + 6\,p w t_1 t^2_2 E k + (w t_1 t_2 E k)^2}{p^2\,(2\,t_2 + t_1)^2 + 4\,p w t_1 t_2 E k\,(2\,t_2 + t_1) + 3\,(w t_1 t_2 E k)^2}\,F = C_1''''' F\,..(23)$$

$$X_2 = \tfrac{1}{2}\,\frac{p w t_1 t_2 E k\,(t_1 + 2\,t_2) + (w t_1 t_2 E k)^2}{p^2\,(2\,t_2 + t_1)^2 + 4\,p w t_1 t_2 E k\,(2\,t_2 + t_1) + 3\,(w t_1 t_2 E k)^2}\,F = C_2''''' F\,..(24)$$

and,

$$X_3 = \tfrac{1}{2}\,\frac{p^2 t_1\,(2\,t_2 + t_1) + 3\,p w t^2_1 t_2 E k + (w t_1 t_2 E k)^2}{p^2\,(2\,t_2 + t_1)^2 + 4\,p w t_1 t_2 E k\,(2\,t_2 + t_1) + 3\,(w t_1 t_2 E k)^2}\,F = C_3''''' F\,..(25)$$

in which, X_1 X_2, and X_3 are the forces transmitted to each cover-plate by the rivets, numbered from the outside of the joint.

Comments

Formulas similar to Equations (7) to (25) could be developed for any number of rivets in a butt-joint or a lap-joint with equal or unequal thicknesses of plates and different pitch of the rivets. The principle is always the same, the equations are of the first degree, and their number equals the number of unknowns; but the results are complicated.

One point of distinction between compression joints and tension joints may be noted. In the formulas, w signifies the gross width of the strip only in the case of a compression joint, whereas, in the case of a tension joint, it must be taken as some value between the gross and net widths, depending on the pitch of the rivets, p.

For a small pitch, such as three diameters of the rivet, it is suggested that w be taken as, $w = (W - d)$, or $w = \left(W - \frac{3}{4}d\right)$, in which, W is the gross width. For a large value of p, such as $6d$, for example, it would be reasonable, perhaps, to take $w = W - \frac{d}{4}$, approximately. Possibly the formulas become less accurate for tension when the values of p and w are comparatively small.

The writer has assumed tacitly that cross-sections of the joint remain plane and at right angles to the acting force. This assumption is essentially correct except at the part of the plate immediately surrounding the rivet shank. This factor, however, does not seem to be of such importance as to invalidate the formulas.

PART III.—NUMERICAL VALUES OF THE FORCES OF THE RIVETS

To state that inner and outer rivets do work unequally does not mean much unless the amount of that inequality is known; and in order to find it the numerical value of the rivet coefficient, k, must be determined by experiment. Lacking experimental data, however, an approximate mathematical derivation has been made.

In lap-joints, the coefficient, k, as is evident from Equation (7), is the deformation of a rivet that develops a unit force; in double-strap butt-joints, k is the deformation of a rivet transmitting a unit force to each splice plate.

When deformation occurs at a rivet it is due to one or all of the following three causes: (*a*) The axis of the rivet becomes curved due to shear and moment; (*b*) the surface of the rivet becomes crushed; and (*c*) the bearing surface of the rivet hole becomes crushed and distorted. These three factors combined allow the plates to slip relative to each other. As a result of a rather long mathematical analysis (which is omitted), the following expressions were obtained for the rivet coefficients in a tension lap joint composed of plates of equal thickness, t:

$$k = \frac{1}{7\,315\,d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

and,

$$k = \frac{1}{10\,850\,d \tanh\left(2.3\,\frac{t}{d}\right)} \quad \ldots\ldots\ldots\ldots\ldots (27)$$

Equations (26) and (27) were developed by considering the deformed rivet as a beam with fixed ends, loaded along its length with a continuous load, of a magnitude at each point, proportional to the amount of crushing. For comparatively long rivets, the shear deformation is of little importance, while for the short rivets, on the contrary, the bending deformation need not be taken into account.

Accordingly, Equation (27) takes no cognizance of bending, and, with $\frac{7}{8}$-in. rivets, it should be used for values of $t = \frac{1}{2}$ in., or less, while Equation (26), developed by neglecting shear, should be used with the same diameter of rivets for values greater than $t = \frac{1}{2}$ in.

For a two cover-plate butt-joint with a main plate thickness of t_1 and a cover-plate thickness of t_2, the rivet coefficient, k, must be taken as the average of the two values obtained from Equations (26) or (27), using for t the values, $t = \frac{t_1}{2}$ and $t = t_2$, respectively.

It is not claimed that these formulas for k are very accurate; nor is it believed that any formula could be derived taking all contributing factors into account. It would need to be tested experimentally. The rivet hole may be irregular; the shank of the rivet may not completely fill it; and the driven rivet may leave space around it in cooling. All these factors tend to complicate the problem of determining a mathematically accurate value of the coefficient.

Even allowing for these influences, however, and not taking the friction force of the rivet into account, the coefficient, k, must vary to some extent with the force, since inelastic deformations begin very early because of the high bearing stress on the plate in the middle of the rivet. However, the writer thinks that the values of k in Equations (26) and (27) are not entirely misleading and that they are useful for demonstrating the great differences in the work done by rivets, which ordinarily are assumed to work equally. Table 1 has been prepared for this purpose by means of Equations (9) to (25), using values of k from Equations (26) and (27). In Table 1, C is the fraction of the total force taken by each rivet, according to conventional design (reciprocal of the total number of shears in the joint) and C_1, C_2, and C_3 are fractions of the total force taken by each rivet, as given by Equations (9) to (25), inclusive. The percentage of over-stress is listed in the last column.

* Any value.

The equations herein presented, with the values given in Table 1, lead to four conclusions, as follows:

1.—The standard practice of dividing the force in proportion to the shearing areas of the rivets and disregarding the deformation of the plates leads to results that are very inaccurate. In a 6-rivet lap-joint the over-stress of an outer rivet designed by the conventional method may be more than 100%, and in a joint with a greater number of rivets, the over-stress seems to be still greater.

2.—Actually, the total force acting on a riveted joint is not distributed equally among the rivets; a larger proportion of the total work is done by the outer rivets.

3.—The proportion of total work in the outer rivets increases as the pitch and diameter of the rivets increase and the cross-section of the plates decreases.

4.—If there are many rivets in a longitudinal row the inner rivets are inefficient, and an increase in the number does not improve the value of the joint appreciably. For example, in Table 1, comparing the values for 5-rivet and 6-rivet joints, it is seen that when the number of rivets is increased from five to six (that is, by 20%), the force on the outer rivet decreases only by 2.3%, 0.6%, 6.6%, and 3.3%, in the four cases given.

It seems likely that in joints containing twenty or more rows of rivets, some of those in the middle perform no work and those on the outside are over-stressed greatly. However, no engineering structure has ever failed because of this lack of uniform distribution, due to the ductile nature of structural steel. After the outer rivets have been stressed beyond the elastic limit, they do not break, but deform almost without increase in stress, and this brings the inner rivets into play. If the rivets were made of some brittle material, the inaccuracy of the conventional design method would soon manifest itself in the failure of the rivets.

Another factor that helps the outer rivets is friction between plates, which has been disregarded entirely in this analysis. Actually, as was seen in the beginning of this paper, the rivets do part of their work by friction which involves no deformation and retards the moment when the stress in a rivet exceeds the elastic limit.

The method of distributing a force through the rivets of a joint as presented in this paper, might prove of practical value in the design of boilers, tanks, and similar structures. The necessary coefficients could be computed quite easily for standard values of pitch, width of plate, thickness of plate, diameter of rivet, and for type of joint. Such data could then be plotted into curves for the uses of the designer. As stated previously, the rivet coefficient, k, would be determined by experiment.

Of course, the greatest disadvantage of the method is that it is less economical than the present standard method of equal distribution. Furthermore, the writer does not recommend it for general structural design of buildings, bridges, etc. In this field, serious complications arise because of the variable pitch and spacing of rivets, because of the use of structural shapes other than plates, because of the irregular shape of gusset-plates, and because of several members meeting at the same point.

However, the writer ventures to offer for discussion a few suggestions concerning the standard design of connections of structural members, in the hope of promoting conditions that will insure more uniform distribution of forces among the rivets, namely:

(1) In compression members, the number of gauge lines should be increased. This would reduce the number of rivets on each gauge line, and hence the inequality of forces taken up by the rivets. Naturally, it would be more difficult to apply this recommendation to the tension members, due to the consideration of the net section.

(2) A minimum allowable longitudinal pitch should be established, since the inequality decreases with the decrease of pitch. Although this is being generally done in common structural practice, sometimes the pitch is lengthened due to a desire to eliminate an extra cut on the gusset-plate.

(3) The number of rivets to be placed on a gauge line should be more or less proportional to the cross-sectional areas at those gauge lines. Thus, in Fig. 5, the number of rivets on Gauge Lines 1 and 5, are just sufficient to develop the angles. These rivets are over-stressed because of the greater cross-sectional areas that are related to these gauge lines, including angles and parts of the plate.

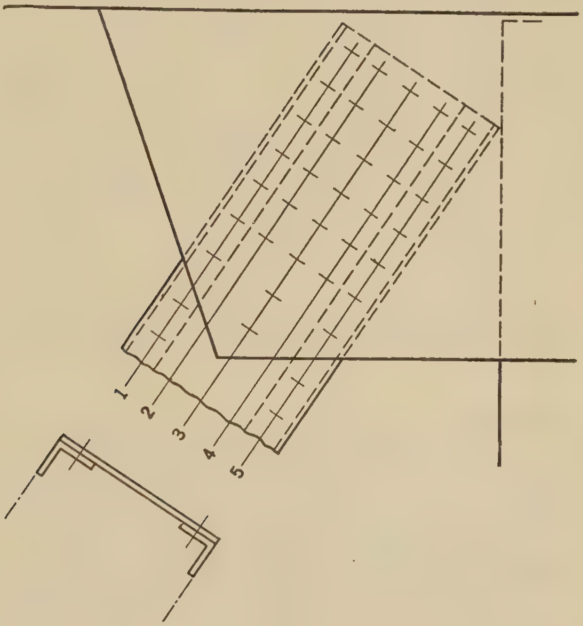

FIG. 5.

ACKNOWLEDGMENT

While this problem has been treated in a general way previously,[2] the methods developed in this paper resulted from independent studies.

The writer wishes to acknowledge his indebtedness to A. H. Finlay, Assoc. M. Am. Soc. C. E., for invaluable guidance and criticism during the preparation of this paper.

DISCUSSION

Henry W. Troelsch,[3] M. Am. Soc. C. E. (by letter).—The problem of the distribution of stress in riveted joints, which Mr. Hrennikoff considers in this paper, is similar in many ways to the problem of the distribution of shear in welded connections, dealt with by the writer in the companion paper.[4] The two are in fact special cases of a more general problem. The only difference is that, for the riveted joints, the connection between the spliced members is assumed to exist only at uniformly spaced points (the rivet centers), while for the welded joints, the connection is assumed to extend uniformly from one end of the joint to the other. In both cases it is assumed that the deformations of the bars and of the connecting members (rivets or welds) are proportional to their stresses.

The similarity of the two theories can be shown by applying the weld theory to several of the riveted joints analyzed by Mr. Hrennikoff, and comparing the results. Let each rivet be replaced by a single weld, equal in length to the pitch, and having the same rigidity as the rivet. The length, z, of the equivalent welded joint will then be the number of rivets multiplied by the pitch. The "detrusion ratio", D, becomes $\frac{1}{kp}$. The shears per unit of length at the rivet centers can then be obtained by Equation (15). These shears multiplied by the pitch will give approximate values of the forces acting on the rivets.

TABLE 2—Comparison of Distribution Coefficients, C, as Determined by Weld Theory and Rivet Theory

Number of rivets	Width of strip, w, in inches	Pitch of rivets p, in inches	Thickness of plate, t, in inches	Rivet coefficient, k, in inches per kip	Detrusion ratio, D, in kips per square inch	Length of equivalent weld, z, in inches	Distribution Coefficients			
							Theory	C_1	C_2	C_3
6......	3	2.5	1	$\frac{1}{6\ 400}$	2 560	15	Weld...	0.239	0.146	0.107
							Rivet..	0.241	0.149	0.110
6......	3	5	0.5	$\frac{1}{8\ 200}$	1 640	30	Weld...	0.344	0.0907	0.0291
							Rivet..	0.3596	0.1036	0.0368
3......	3	2.5	1	$\frac{1}{6\ 400}$	2 560	7.5	Weld...	0.347	0.293	......
							Rivet..	0.351	0.298	......
3......	3	5	0.5	$\frac{1}{8\ 200}$	1 640	15	Weld...	0.373	0.181	......
							Rivet..	0.395	0.210	......

The results for four cases are shown in Table 2, in which the values marked "Weld Theory" were obtained as indicated herein, while those marked "Rivet Theory" are the corresponding coefficients taken from Mr. Hrennikoff's paper. The close agreement between the two theories is brought out even more clearly in Fig. 6, which shows the same four cases. The ordinates to the dotted curves are the shears per inch in the equivalent welds, while the ordinates to the plotted points are Mr. Hrennikoff's rivet coefficients divided by the pitch. Fig. 6 shows that if the assumptions underlying the theories are fulfilled, the distribution of the shear follows the same general law, whether the joint is riveted or welded.

FIG. 6.—AGREEMENT BETWEEN WELD THEORY AND RIVET THEORY.

HENRY B. SEAMAN,[5] M. AM. SOC. C. E. (by letter).—The analysis presented by Mr. Hrennikoff treats of a subject that has long claimed the attention of designers of riveted trusses, and explains the preference of many engineers for the pin-connected type, even for the shorter spans. In the earlier days of American bridge construction the pin-connected type was used for spans as short as 80 ft., and gave great satisfaction in maintenance; but the preference of the shops for less labor, with heavier tonnage and correspondingly lower shop costs, brought the riveted truss into its present favor.

It was in 1886 that the matter first claimed the attention of the writer, in a riveted lattice girder of about 50-ft. span, for an elevated railway. There were five rivets in the joint, and the writer preferred to place the odd rivet in the center of the cluster, leaving two end rivets to take the initial strain. When the matter was referred to the late Theodore Cooper, M. Am. Soc. C. E., however, he preferred that the single rivet be placed on the outside so as to save material by the cutting of one hole, instead of two holes. This well illustrates the difference between first cost and subsequent cost of maintenance.

The objectionable differences in the stresses of the rivets of a joint, explained by Mr. Hrennikoff, do actually exist in all riveted joints.

---

[5] Cons. Engr., Brooklyn, N. Y.

A. H. FINLAY,[6] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper, Mr. Hrennikoff has done a service in calling attention to the weaknesses of the assumptions underlying the common analysis of riveted joints. A periodical review of the assumptions that underlie various structural theories is of the greatest importance, since it is a human failing that, given sufficient time for their assimilation, assumptions at first viewed even with some misgiving eventually tend to be confused with the eternal verities.

In Part I the author has given a clear discussion of the probable behavior of rivets in a joint. Part II translates into the more imposing symbolism of mathematics the assumptions of Part I for the specific case of no friction between the plates.

The wisdom of omitting from consideration the friction between the plates will scarcely be challenged. To any one who has watched rivets being driven with a so-called "bull-riveter" and who has seen the air pressure removed, as is commonly done, within 2 or 3 sec of its first application, the stretching of the still incandescent rivet shank by the spring of the plates upon removal of the pressure, is full of significance.

The writer feels that special credit is due the author for his mathematical evaluation of the proportionality factor expressing the ratio of rivet slip to rivet stress, or k, without which his results would have been merely interesting qualitative relationships. The lack of specific values of this quantity has greatly handicapped previous work in this field. As to the correctness of the author's two values for k, one can only expect that they approach the truth as closely as do the very necessary assumptions, under cover of which the obviously difficult mathematical problem was attacked. The author wisely omits the analysis and modestly refers to it as "rather long."

The writer agrees that the determination of k is a proper field for experiment, and he would be interested to hear of any tests in this connection, although he feels that, in practice, the values of k are as divergent as the conditions of driving.

The general satisfaction given by riveted joints as at present designed as well as the simplicity and economy resulting from them are sufficient guaranties that no radical changes in design will be made. It would be unwise to think of penalizing structural steel for one of its greatest virtues—ductility. How many discordant elements this quality reconciles may never be known, but structural engineers have good reason to appreciate its existence.

With regard to the author's several suggestions for the improvement of riveted joint design, the writer feels that, while in all joints a more uniform distribution of stress will result among the rivets, there is danger of a poorer distribution of stress occurring across the gusset-plate, owing to the more compact rivet groups and the general tendency to bunch rivets which is implied.

F. P. SHEARWOOD,[7] M. AM. SOC. C. E. (by letter).—This paper deals with one of the many problems encountered in structural design whenever riveted joints are closely investigated. They often worry the designers, but by general consent the elasticity and ductility of the joint are depended upon to distribute the strain safely. While such easy method has been recognized and used, it would be more satisfactory to understand and picture what the strains are likely to be, so that designers can proportion and group the rivets and material to obtain the greatest safety.

[7] Chf. Engr., Dominion Bridge Co., Ltd., Montreal, Que., Canada.

Mr. Hrennikoff has given a clear and useful theory for calculating the rivet strains. His theory is based on perfect elasticity throughout the entire joint. If the initial resistance is from friction, however, and if there is some clearance in the rivet hole, the distribution will not be truly elastic and, when relieved of its load, the joint will not completely recover.

Although the author has referred to friction between the plates, he has disregarded it in his analysis. This may be of the greatest importance, however, in preventing over-stressing rivets in long joints. If there is any clearance between the rivet and its hole, and frictional resistance is about equal to the working value for single shear, the stress at any rivet can not exceed the working value, until the clearance is absorbed by slipping.

The author states that long joints are constantly being used and that none of them has failed. This fact has been proved so often that it has become standard practice to assume that the stress in a joint is equally distributed to all the rivets; that is, that the strength of a riveted joint is the sum of the individual rivet values. It is the general opinion, however, borne out by experience, that connections resisting severe reversals of stress will become loose, and, therefore, must be proportioned differently. These facts indicate that there is some straining effect that is not elastic and that produces wear; and it clearly points to a slip taking place between the plates, or between the plates and the rivet heads. Frictional distortion or slip of the plates caused by stress in the member will not recover on the removal of the stress, unless there is as great a difference between the strains in the plates as that which caused the slip.

To allow slip to take place without shear in the rivets there must be clearance between the rivet and the hole. That this exists seems very probable. When a rivet is driven its heat temporarily reduces the size of the hole. The rivet is upset to the size of the heated hole, and pressure is released from both the hole and the rivet when they are at a high heat. Both the hole and the rivet must cool, and, therefore, a clearance is likely. As an illustration, let it be assumed that when the driving of a rivet is completed there is an average temperature of 500° above normal temperature in the edges of the hole at the shank of the rivet; then the clearance for a $\frac{7}{8}$-in. rivet will be approximately: $0.0000065 \times 500 \times 2 \times 0.875 = 0.00525$ in. That means that the plates can move past each other 0.005 in. before the rivet touches the walls of the hole and it is strained in shear or bearing.

The amount of frictional resistance will depend on the initial tension developed in the rivet by cooling. It seems probable that this tension on the rivet head is about equal to the elastic limit of the material, say, 35 000 lb per sq in. By assuming the coefficient of friction at 20%, the resistance at each surface will be $35\,000 \times 0.6 \times 0.2 = 4\,200$ lb.

To enable the plates to move, at least two surfaces are affected; therefore, the force required to overcome friction will be equal to about 8 400 lb per rivet. Fig. 7 illustrates the clearances, relative positions, and strains in the holes of an 8-rivet lap-joint, under various conditions of loading. The joint is composed of two 1-in. by 3-in. plates. In order to simplify the computations, the force required to overcome friction is assumed equal to 7 500 lb per rivet, or 2 500 lb per in. of width, and $E = 30\,000\,000$ lb per sq in. The plates are shown extended an amount equal to 0.00033 in. per 10 000-lb strain, or 0.001 in. per 10 000-lb strain between rivets. Stresses are given in pounds per square inch of material. Fig. 7(*a*) illustrates the clearances in the holes to a very exaggerated scale. The total clearance between the hole and rivet is assumed to be 0.0025 on each side, or 0.005 in all.

Fig. 7(*b*) gives the relative positions and strains of the two plates when a stress of 20 000 lb per sq in. of the main plate is applied (full section is assumed at holes). When this load is applied, the frictional resistance of one rivet will be exerted at Rivet *a*, but as this is insufficient to equalize the strain in the two plates they will slip past each other, and a load of 17 500 lb per sq in. will remain in the upper plate until the resistance of Rivet *b* is met, where another 2 500 lb per lin in. (the resistance from one rivet) will be transferred to the lower plate, and so on, until the strains in the two plates are equal.

The difference of deformation in the upper and lower plates between the point where the strains are equal and any rivet in the connection will give the amount of slip at that point. In this example, the slip at Rivet *a* equals 0.003 in., leaving a clearance of 0.001 in. between the hole and rivet. At Rivet *b*, it is 0.0015 in., and at Rivet *c*, 0.0005 in., while at Rivet *d*, there is no slip because the strains in the plates are equal. Some clearance still remains at all these rivets and, therefore, no shearing can have been developed in the rivets themselves. The bending resistance in the rivet due to its heads slipping on the plates cannot be very much. If it is disregarded there can be no stress of any kind in the rivet, until the slip of the end rivet has exceeded the clearance in the hole.

Fig. 7(*c*) illustrates the positions and strains when 50% of the stress is removed. No alteration in the relative positions of the two plates is necessary to keep the friction below the slipping value of 2 500 lb and, therefore, no slip or wear results. When more than 50% of the load is removed the plates must slip to reduce the friction to 2 500 lb. Fig. 7(*d*) shows the positions and strains resulting when all the stress is removed, and it shows also that Rivets *a* and *b* have partly slipped back. The 20 000-lb unit strain assumed in this example does not often occur in actual practice, and it is probable that the ordinary range of strains developed will not be sufficient to slip the plates back and loosen the rivets by wear.

When the stress exceeds the frictional value of all the rivets the entire connection will slip until the end rivets come into contact with the walls of the holes. These end rivets must resist the excess of stress over the friction value of all the rivets until the deformation of these end rivets is sufficient to bring the next rivet into contact.

FIG. 7.—CLEARANCES, RELATIVE POSITIONS, AND STRAINS IN HOLES OF AN 8-RIVET LAP-JOINT.

Fig. 7(*e*) gives the clearances in the holes when this connection is stressed to slightly beyond the total friction value of the eight rivets. The rivets at each end must transfer 5 000 lb per sq in., which is twice the assumed friction value of the rivet friction; but there is still clearance at the second rivets. (No allowance has been made for the deflection from shearing and bearing of the end rivets.)

For the sake of simplifying the general picture of slippage, these examples of lap-joints are based on the assumption that the rivet heads slip on the plates at one-half the resistance and displacement that the plates slip past each other. The resistance from the bending of the rivet is also neglected.

If a butt-joint is examined it will be found that the same general slipping takes place, except that the plates will first slip on one another until the rivet shank bears against the inner plate. The heads will then slip in the outer plates, and two extra slipping surfaces will be brought into resistance, until the end rivet is jammed between the three plates and any further resistance must be entirely taken up by the end rivets in shear until the deformation is sufficient to bring the next rivet to bear on the walls of its hole.

Fig. 8 is a corresponding example of a butt-joint. The force required to overcome friction is assumed to be equal to 3 750 lb per rivet on each surface, or 1 250 lb per rivet on each surface per inch of width. As in Fig. 7, stresses are given in pounds per square inch of material. It can be readily seen that the friction between the plates at all the rivets and the friction between the rivet heads and plates at Rivets *a* and *d* are just sufficient to resist the load, while at Rivets *b* and *c* some clearance still remains. (*a*) NO LOAD (BEFORE STRESSING)

(*b*) LOAD OF 60 000 LB (20 000 LB PER SQ IN.)

(*c*) LOAD OF 30 000 LB (AFTER STRESSING TO 20 000 LB PER SQ IN.)

(*d*) NO LOAD (AFTER STRESSING TO 20 000 LB PER SQ IN.)

FIG. 8.—CLEARANCES, RELATIVE POSITIONS, AND STRAINS IN HOLES OF AN 8-RIVET BUTT-JOINT.

load will be entirely taken by Rivets *a* and *d* in shear until the deformation of those rivets amounts to the clearances remaining at Rivets *b* and *c*. In the case of the butt-joint the resistance to recovery when the load is removed is greater than in the case of the lap-joint.

The stresses and dimensions of clearances are only approximate and are used to illustrate, in the simplest way, the possible workings in a riveted joint, which has minute clearances in the holes when under stress. They also illustrate the fact that very unequal distribution of stress among the rivets of a group is not probable in the usual length of riveted connections.

The problem of how much the frictional resistance amounts to and what range of stress can be used without producing constant slip, depends on a great number of variable uncertainties and would be difficult to solve by mathematics. Experience indicates that the range can be almost up to reversal without producing wear, and general practice has largely assumed this in designing riveted structures. The main problem is, as to whether there is any clearance in the rivet holes, and, if so, how much?

The writer has endeavored to show: First, that there is clearance between the hole and the rivet and that this clearance must be absorbed before the rivets can take any shear; and, second, that slipping of the connected plates occurs and that the force to produce this movement is consistent; that is, it does not vary with the amount of movement. If these are the facts and the deformation required to equal the clearance is sufficient to absorb the total strain in joints of usual length, Mr. Hrennikoff's theory, which is based on the elasticity of the rivets and material, does not function, except for a small part of the stresses in very long joints.

W. P. Roop,[8] M. Am. Soc. C. E. (by letter).—It is an opportune moment for re-opening discussion of riveted joints. Comment of two kinds is presented herewith, namely, another solution of the specific problem of this paper, and a more general discussion of experimental methods and data.

The consideration of relative deformations in different parts of a riveted joint is an important departure from practice in conventional design, and one which leads to some rather unfamiliar points of view.

Point Rivets.—The author's conception of a rivet appears to be that of a point or small area in which there is no relative motion of the faying surfaces with respect to each other at loads below limiting friction; when this limit is exceeded relative motion occurs to the extent that resistance due to friction and to elastic deformations in plates and rivet will permit. This elastic resistance is considered to be proportional to the amount of the relative motion, or slip.

From this as a starting point, the author develops formulas for action of rivets in a lap-joint in tension. Couples due to the eccentricity of the tensions in the two plates are ignored, which is more or less equivalent to splitting a double-strapped joint down the center of the plate, so as to obtain only one strap in the picture. Fig. 3 shows the assumed relative deformations.

---

[8] Lieut. (CC), U.S.N.; New York Shipbuilding Co., Camden, N. J.

Diagrams of this kind form a convenient basis for the entire discussion, and their character should be defined a little more clearly. It is preferable to adopt the mid-length of the lap as the point of reference, and in order to obtain complete symmetry this point is taken half-way between the points at mid-length of the two sides of the lap. On Fig. 3 this point would be represented midway between Points Q and W. Distances in the diagram measured vertically from a horizontal line through this point represent horizontal displacements, and as the diagram is drawn, distances laid off upward represent displacements to the left, and *vice versa.*

A somewhat different graphical representation of this situation is obtained by drawing two parallel lines representing the two sides of the surface of contact (faying surface) in the lap. Although actually these two surfaces coincide, the lines representing them are separated, in Fig. 9, by a convenient distance. To each point in one plate, P, there corresponds a point, P', in the other plate; in the unloaded condition of the joint these two points coincide, and in Fig. 3 a line joining them would be normal to the base lines, but when the joint is loaded, all these lines are inclined. Conventional design is based on the idea that the inclination, $P\,P'$, is uniform throughout the joint, so that all rivets are equally loaded. However, this is impossible except in a limiting case, such as that where contact between the plates is at two points only, the load being equally shared at these two points. Otherwise, the relative displacement of one plate with respect to the other is more complex.

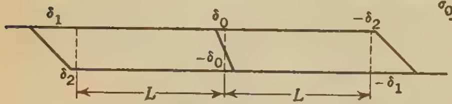

FIG. 9.—DEFLECTIONS

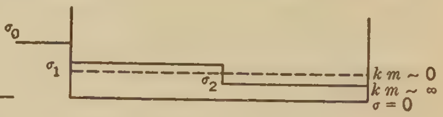

FIG. 10.—STRESSES

In a diagram of the type used by the author the case of two (rows of) point rivets would be represented by two horizontal lines at equal distances above and below the base. The case of three point rivets is that of the author's Example 1.

Graphical interpretation may be given to the results expressed in Equations (9) and (10). When k is small and the rivets are stiff, the lines, $M\,O$ and $S\,U$ (Fig. 3), are nearly straight. The value of l is also affected, and in the limiting case of $k = 0$, becomes equal to $F\frac{p}{wtE}$. The middle row of rivets then carries no load, and $M\,O$ and $S\,U$ are horizontal. As k increases, and the connections in the lap become more flexible, $M\,O$ is inclined and N departs from the straight line joining M and O. When $k = 3\frac{p}{wtE}$, l has already reached a value slightly negative, namely, $-\frac{1}{11}\,F\,\frac{p}{wtE}$, and as k continues to increase, l will reach larger negative values, approaching $-\frac{kF}{3}$, and the inclination of $M\,O$ will increase indefinitely.

It is for such reasons that the writer prefers another type of diagram instead of that used by Mr. Hrennikoff. In this third type of diagram the horizontal co-ordinate is still length, measured both ways from mid-length of the joint. Let the entire length of the joint be $2L$, and the distance from mid-length to a given section of the joint, ξ; then a convenient co-ordinate to use is $X = \frac{\xi}{L}$, since it is applicable to a joint of any length, and the joint lies between the limits, $-1 < X < +1$. For a vertical co-ordinate, however, the writer chooses stress in the plate. In the author's notation, this is $\frac{F}{wt}$, and will be denoted by σ, with subscripts, 1 and 2, for the upper and lower plates. The stress in either plate outside the joint is σ_0, and a moment's reflection will show that in a lap of plates of equal thickness, $\sigma_1 + \sigma_2 = \sigma_0$, at all values of X. With any symmetrical arrangement of the connections, at $X = 0$, $\sigma_1 = \sigma_2 = \frac{\sigma_0}{2}$. Between point rivets, σ_1 and σ_2 will have uniform values, so that the curve will be, for σ_1, a series of steps downward from σ_0 at $X = -1$, with a riser at each intervening rivet, landing on $\sigma_1 = 0$ at the last rivet on the right, where $X = +1$.

With two rows of rivets, σ_1 drops immediately at $X = -1$ to $\frac{\sigma_0}{2}$ and retains this value until $X = +1$, when it drops to 0. With three rows of rivets expressions for σ_1 and σ_2 may be obtained by a process similar to that used by the author. The deflection of a point rivet, δ, is proportional to the tensile stress (in the plate) which produces the deflection, thus $\delta = k\sigma$. This tensile stress also produces elongation in the plate according to an equation of the type, $d = \frac{\sigma}{m}$. Thus, k is the inverse stiffness of the rivet in shear, and m is the elastic modulus of the plate. The solution is,

$$\sigma_1 = \sigma_0 \frac{2\,k\,m + 1}{3\,k\,m + 2}$$

When k and m are large, the rivets slender and flexible, and the plates thick, σ_1 is nearly two-thirds σ_0, and each of the three rivets carries about one-third the total load. When k and m are small, the rivets large, and the plate thin, σ_1 is about one-half σ_0, and the middle rivet carries little load. Fig. 10 exhibits this graphically. The stress in the other plate at the same point, X, is σ_2, or, on account of symmetry, it is the stress in the same plate at $X' = -X$.

By similar methods a solution can be found for a joint with any number of rows of point rivets, but the elimination of deflections will require solution of a correspondingly large number of linear equations. This will lead to a uniform value for σ_1 in each interval of plating between rows. These values will drop from σ_0 to 0 by a corresponding number of steps; when $k\,m \sim \infty$, the load will be shared about equally by all rivets, and when $k\,m \sim 0$, the outer rivets will take practically all of it.

Distributed Connection.—Now the point rivet, on which this entire analysis is based, is a rather crude abstraction. The area of the holes alone in a lap-joint may run to 13% of the area of the lap, and the area under high heads and points may double that figure. Further, the clamping effect of a rivet is surely not limited to the area under the head. In studying this question the writer has approached it with the assumption that at moderate loads the clamping area is 100% of the lap, and that as slip sets in, it starts at the edges where the stress concentrations occur, and spreads inward. He has further assumed that even in the area of contact the deflections in the parting between the plates are large compared with the variations in stress through the thickness of the plate. Such an assumption is necessary, in order to make any analysis of this character possible, but instead of connection between the plates only at isolated points, assume the elastic resistance to tension to be distributed continuously over the entire area of the lap.

The full analysis for this case has been worked out, but only the results and definition of the quantities will be given herein. The stiffness of the elastic connections must now be expressed in terms of elastic resistance per unit length of the joint (parallel to the load), and also, of course, per unit deflection. The quantity, k, will be defined, as before, in an inverse relation, so that a high value of k is associated with large deflections under a given load; m retains the same meaning as before, being in direct proportion to Young's modulus for the plate, but depending also on dimensions of the joint. The solution is in the form,

$$\sigma_1 = \frac{\sigma_0}{2}\left[1 - \frac{C}{C^2 - 1}\left(C^X - C^{-X}\right)\right]$$

As before, when $X = 1$, $\sigma_1 = \sigma_0$; when $X = 0$, $\sigma_1 = \frac{\sigma_0}{2}$; but instead of changing by a series of steps, the stress now varies continuously, following a curve the course of which depends on the value of C. This, in turn, depends on the elastic characteristics of the joint according to the equation:

$$C = e^{\sqrt{\frac{1}{km}}}$$

Thus, when km is large, the elastic connection flexible, and the plates thick, C approaches unity, log C approaches zero, and C^X approaches $1 + X \log C$. Then,

$$\sigma_1 = \frac{\sigma_0}{2}\left[1 - \text{Constant } X\right]$$

and since $\sigma_1 = \sigma_0$ when $X = -1$, and $\sigma_1 = 0$ when $X = +1$, the constant must be -1. On the other hand, when km is very small, C is very large, and:

$$\sigma_1 \sim \frac{\sigma_0}{2}\left[1 - C^{X-1} + C^{-X-1}\right]$$

It is easy to see how σ_1 varies with X at various values of km by writing a few numbers. For example, when $km = 0.01$, σ_1 has dropped off to 0.57 at $X = -0.8$; and as $km \sim 0$, the curve would approach a vertical drop to

$\sigma_1 = \frac{\sigma_0}{2}$, following along this value until the other end of the joint was approached. In Fig. 11, $\frac{\sigma_1}{\sigma_0}$ is plotted on X for various values of km.

This solution appears to make a somewhat closer approach to the truth than one based on point rivets, but it still departs from the truth in assuming that the elastic connections between the plates are distributed all over the area of the lap. The connections are doubtless actually somewhat spotty, and actual stress distributions would be affected. Nevertheless, the main feature of the results must hold in actual cases also, such as a concentration at the edges of the lap which always exists, but is more pronounced when plate edges are clamped tightly and the plate itself is relatively extensible. Over-all extensions under load have also been calculated both for point rivets and distributed clamping. Discussion of this matter, however, is reserved for the present.

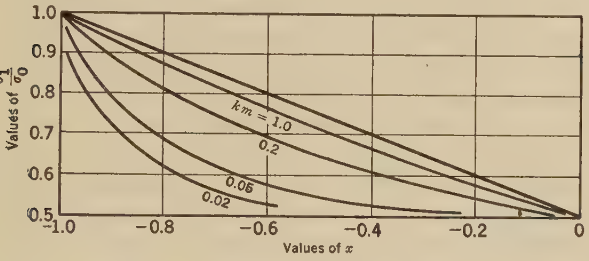

FIG. 11.—DISTRIBUTED CONNECTIONS.

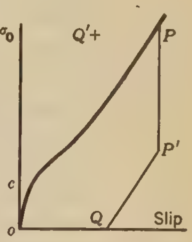

FIG. 12.—SLIP CURVE.

The next step in the analysis of a lap-joint would lie in consideration of the distribution of stress across the thickness of the lapped plates, which obviously cannot be uniform. This would lead still deeper into the theory of elasticity, although the question is also accessible to study by the photoelastic method. Purely analytical study of riveted joints in this field appears to have about reached its present limit. In fact, the object of such calculations as these is not to obtain conclusions directly applicable in the design of joints, but rather to obtain a nominal analysis sufficiently close to the truth to permit its use in reduction of experimental data and evaluation of empirical constants.

Experimental Studies.—All experiments have from necessity dealt with entire joints and not with such abstractions as point rivets. Perhaps it may become possible to study experimentally the separate elements of a riveted joint, but for the present designers are practically limited to judging the correctness of analysis by the extent to which it leads to correct reconstruction of data observed for whole joints. Such data have been available for a long time as far as ultimate strength is concerned, but, unfortunately, other data which are of more significance than the ultimate strength, have been obtained only to a limited degree. By this are meant in particular data on stresses at working loads, and on elongations. That these are more significant than ultimate strength of isolated joints will be apparent from the consideration that (at least in ships) a joint seldom works in isolation, but is almost always in combination with other elements of construction in such a way that relative deformations are of primary significance. Further, after elastic limits have been passed, even an isolated joint works in an entirely different way from that by which working loads are resisted. No doubt the basic assumption of conventional design, that all rivets share the load equally, has some justification as far as the ultimate strength of a lap-joint goes. For such a joint as that shown in the author's Fig. 2, however, such an assumption is not even approximately correct, and even in the simple lap-joint, under working loads, inequalities in rivet loading, such as the author points out, have important consequences.

Experiments in which elongation and stress distribution were observed, were contemplated as long ago as 1869.[9] Known to the writer in detail are only two series of tests in which serious efforts to observe elongations were made, namely, those of Montgomerie,[10] and those made at the Bureau of Standards by Commander E. L. Gayhart, for the Bureau of Construction and Repair, U. S. Navy Department,[11] which will be referred to as the "1924 tests." No doubt similar studies have been made, and are known to others.

In all discussion of the elongation of riveted joints prominence is given to the word, "slip." It is important that its meaning should be agreed upon. In early tests a fine line was scribed across the parting at the plate edges and observed with a glass. When the continuity of this line was observed to be broken, slip was said to have begun. Close observations of slip on this basis, taken on a series of lines spread over the length of the joint, with the help of a micrometer microscope, might produce results of value, and as far as the writer knows this has never been undertaken.

Since over-all elongation of the joint is, for many purposes, the significant quantity, slip has sometimes been taken to be the remaining elongation on release (but not reversal) of the tensile load. This is based on the idea that this phenomenon is due to having exceeded a critical frictional resistance somewhere, which permitted sliding of the plates over each other; release of load would not be sufficient to remove such a deformation which would thus appear as a permanent set. For observation of slip on this basis, however, release is necessary, leading to complicated re-adjustments. For this reason a third view of slip was taken in the 1924 tests.

Instead of simple over-all elongation, deformation was measured as between a number of pairs of points; curves were plotted on load, and a break in the curve, such as that marking proportional limit in a tensile test specimen, was taken to mark the beginning of slip. The amount of slip at a given load between a given pair of points was obtained by subtracting from the extension as observed by a dial gauge a calculated correction for the elastic part of this extension. This calculation was on a rather nominal basis, no great emphasis being placed on its absolute value in view of the numerous other uncertainties involved.

[10] *Transactions*, Inst. of Engrs. and Shipbuilders in Scotland, 1920; also, *Transactions*, Inst. of Naval Archts., 1923.

[11] *Transactions*, Soc. of Naval Archts. and Marine Engrs. (1926), p. 55.

In order to eliminate as far as possible arguments based, not on real differences of opinion, but on differences of definition, the writer proposes that slip be regarded as the kind of a quantity actually observed in the early tests on the plate edges, namely, the distance separating two points on the two sides of the faying surface which were originally coincident. On this basis slip will depend on the entire history of the joint, so that "original condition" means whatever starting point was adopted for the observations. On this basis, slip throughout the area of the joint is not directly amenable to observation. Such data on slip as are inferred from observations should be qualified; thus "edge" slip explains itself. Inferred slip based on the subtraction of a calculated elastic correction might be called "nominal" slip. As defined, slip will vary from point to point throughout the joint; values obtained from data on the extension of the whole joint might be called 'over-all" slip. Perhaps the most important distinction of all is that between residual slip, which is that remaining on release of load, and elastic slip which, generally speaking, would be in direct proportion to the load. More specifically, elastic slip would be defined as the difference between the total slip and the residual slip, relative motion of the plates being under control of the elastic resistance of the rivets.

Armed with this specific view of the nature of slip, the reader may return to view Part III of the author's paper, devoted to "Numerical Values of the Forces of the Rivets."

Accepting the author's demonstration of overstressing in outer rivets, it still seems fair to say that the picture bears little resemblance to the facts until phenomena of friction and slip are considered. Commander Gayhart has shown[12] that over-all slip begins at loads that may well lie within working ranges. The curves as drawn in his paper require attention to the manner in which they are constructed. A type curve is shown in Fig. 12, in which it should be noted that the point plotted at Q' is obtained only at zero external load; it is actually located at Q, but is placed at Q' for convenience. During release the course of the curve is from P to Q. The vertical descent, $P P'$, represents the release of the frictional resistance. However, before the elongation can be reduced, as in passing from P' to Q, a reversed friction must be overcome. The friction, $P P'$, therefore, might be expected to equal twice the critical friction, $O C$. In the case shown in Commander Gayhart's paper it is much greater than this.

Beyond the point at which over-all slip begins, not only elastic slip, but residual slip, increases approximately in direct proportion to total load. These facts lead to questions as to the details of slip action, which must be settled somehow before a theory of riveted joints has even a chance of being correct.

If it could be assumed that friction played no part at loads above that of initial slip, or if the residual slip could be assumed equal to zero, the theory developed by the author would be applicable to the idealized cases considered. Such assumptions, however, are obviously wide of the mark. It is not possible to separate elastic slip from residual slip and then treat the elastic slip as if residual slip played no part in determining elastic reactions. The true analysis of these curves must be based on a separation, not of the elements of slip under a given total load, but of the elements of load under a given total slip.

---

[12] See *Transactions*, Soc. of Naval Archts. and Marine Engrs. (1926), Pl. 22, Sheet 3.

Summary and Conclusion.—The slip curve which has been discussed is not the only type that was obtained in the 1924 tests, but this is not the place for extended discussion of those tests. The principal object of this comment has been to show that rivet action, even to the first degree of approximation, may be considerably more complicated than is contemplated by the author. If sound progress beyond what he aptly calls "conventional design" is to be made, it is essential that more experimental information be made available, and especially that it should receive a searching analysis, with subsequent tests especially devised to provide answers to the questions developed by the analysis. When the results of such study become accessible to those who are directly responsible for detail design the Engineering Profession may perhaps hope to see no more such absurdities as that mentioned by the author—a tensile joint with twenty rows of rivets.

H. N. HILL[13] AND MARSHALL HOLT,[14] JUNIORS, AM. SOC. C. E. (by letter).—The unequal distribution of the load on the rivets in a joint is a matter deserving of greater recognition than is ordinarily accorded it by the Engineering Profession. This distribution has been the subject of an investigation conducted by the writers under the supervision of R. L. Templin, M. Am. Soc. C. E. The investigation concerned the distribution of load in butt-joints comprising splices between plates of steel and a high-strength aluminum alloy, using both steel and aluminum alloy rivets.

The mechanical properties of the two metals used in the investigation are given in Table 3. It may be noted that there is little difference between the strength of the two materials, but that the modulus of elasticity for the aluminum is about one-third that for steel. The problem involved the distribution of the load on the various rivets, not only as affected by the physical dimensions of the joint, but also as affected by the different values of the modulus of elasticity for the two materials.

TABLE 3.—MECHANICAL PROPERTIES OF STEEL AND HIGH-STRENGTH ALUMINUM ALLOY

Properties	Steel	Aluminum alloy
Ultimate tensile strength, in pounds per square inch	59 000	56 000
Yield strength in tension, in pounds per square inch	28 000	33 000
Percentage elongation in 2 in.	37.5	23.0
Modulus of elasticity, in pounds per square inch	29 000 000	10 000 000
Shear strength, in pounds per square inch	45 000	35 000
Shearing modulus, in pounds per square inch	12 000 000	3 800 000

---

[13] Testing Engr., Aluminum Co. of America, New Kensington, Pa.

[14] Research Engr., Aluminum Research Laboratories, Arnold, Pa.

The problem was attacked in two ways: First, an "elastic theory" was developed, along lines similar to those described by Mr. Hrennikoff, taking into account the elastic deformation of the various parts of the joint and assuming the load transmitted by each rivet to be proportional to the relative displacement of the plates; and, second, a number of double-strap butt-joints, embodying a single longitudinal row of rivets, were fabricated and tested to determine experimentally the manner in which the load was distributed among the various rivets.

In establishing a relationship between the deformation and the load on a rivet, the writers have not felt that the limits of accuracy, dictated by the uncertainties existing in any joint, warrant an elaborate mathematical treatment. An experimental determination of the relationship between deformation and load would be of considerably more value than any elaborate mathematical analysis, particularly since the theoretical treatment would require the substantiation of experimental data to make it convincing.

As a basis for the calculations in the mathematical treatment, a relationship between the load and deformation on a rivet was obtained from a preliminary test of a joint, similar to those to be investigated, but having only one rivet on either side of the splice. This specimen was fabricated entirely of aluminum alloy, and consisted of two main plates, 1 in. thick by 5¾ in. wide, two cover-plates of the same width and ½ in. thick, and two ¾-in. rivets. The relative movement of the plates was measured for different loads on the rivets. Although for low loads and relatively high loads, the load-deformation curve was not a straight line, for loads corresponding to the range to be encountered under normal working conditions, differences in the slopes of lines drawn through zero from points on the curve corresponding to the different loads are not great enough to produce an appreciable effect on the results of the calculations.

The results of this test established a relationship between the load and deformation of an aluminum alloy rivet in plates of the same material, but did not cover the other conditions in the joints to be tested. Since the deformation is partly produced by yielding of the plates, a definite load on an aluminum rivet in aluminum plates will produce a greater relative movement than would occur if the plates were of steel. Since the modulus of elasticity of aluminum, is approximately one-third that of steel, it is reasonable to assume that, in a steel specimen of the same dimensions as the one tested, the ratio of deformations would be 1 to 3.

In Table 4 the ratios of load to deformation for conditions other than those covered by this test have been determined by estimating the effects of differences in the conditions. Familiarity with the calculations for determining the distribution of the load among the various rivets reveals the fact that the answer is not extremely sensitive to variations in the ratio of load to deformation of a rivet. Any reasonably correct ratio of load to deformation will give results that are within the range of accuracy to be expected from variations introduced in the fabrication of a particular joint.

It is interesting to note the agreement between the coefficient determined experimentally by the writers and that calculated from the author's equations for the same case. The larger of the two values calculated according to Equations (26) and (27) for the second set of conditions (Table 4) was 0.000182 in. per kip, from Equation (26). Since the author's coefficient for the double-strap butt-joint represents the ratio of the rivet deformation to the load transmitted to one splice plate, and the values in Table 4 are the ratios of rivet deformations to the total rivet loads, in order to make the two comparable it is necessary to divide the author's value by two. This gives the value of 0.000091 in. per kip, whereas a value of 0.00012 was obtained by the writers as one-third of the relative movement determined experimentally for the first set of conditions of Table 4, one-third being the ratio of the modulus of elasticity of aluminum to that of steel.

TABLE 4.—Relations Between Deformation and Load on Rivets

Thickness of plates, in inches	Main plate	Cover-plate	Rivets	Coefficient $\left(\frac{\text{Inches}}{1\ 000\ \text{lb}}\right)$
1 and ½......	Aluminum	Aluminum	Aluminum	0.00035
1 and ½......	Steel	Steel	Steel	0.00012
1 and ½......	Steel	Aluminum	Steel	0.00014
1 and ½......	Steel	Aluminum	Aluminum	0.00030
1 and ½......	Aluminum	Aluminum	Steel	0.00017
¾ and ⅜......	Aluminum	Aluminum	Steel	0.00013
¾ and ⅜......	Steel	Aluminum	Steel	0.00010

Three large riveted specimens were tested, representing splices between a steel plate and one of aluminum. The specimens were 5¾ in. wide, using aluminum cover-plates and embodying five ¾-in. rivets on either side of the splice. The rivets were spaced on 4-in. centers. Details of the three specimens are given in Table 5.

The distribution of the load on the various rivets was determined by measuring the stresses existing in the cover-plates at sections between the rivets, the difference between the load on two adjacent sections being a measure of the load transmitted by the intervening rivet. Strains were measured with a 2-in. Berry strain-gauge on twenty-four gauge lines at each section between two adjacent rivets. The relatively low modulus of elasticity of aluminum permits the accurate determination of comparatively low stresses, the strain in aluminum being about three times as great as that produced by the same stress in steel. The joints were investigated for loads ranging to somewhat above the nominal design load of the specimen, Specimen No. 2, Table 5, being loaded in both tension and compression.

A summary of the results of the tests is shown in Table 5, together with the calculated values of the percentage of the load transmitted by each rivet for a load corresponding to a stress slightly less than the nominal working stress of the joints. The rivets are numbered from 1 to 5, No. 1 being the outer rivet on either end of a joint. Where the main plate and the cover-plates are of the same material and the latter is one-half the thickness of the former, the loads transmitted by the end rivets (Nos. 1 and 5) have been averaged, as have the loads for Rivets Nos. 2 and 4. In the case of the aluminum cover-plates on the steel main plate, however, each rivet transmits a different part of the load (because of the difference in the values of the modulus of elasticity), and the values for each rivet have been listed individually.

* Specimen straightened before test. † Specimen loaded in compression.

Considering the uncertainties that are introduced in the fabrication of such a joint, the results shown in Table 5 indicate a fair agreement between the calculated and measured values for the percentage of load transmitted by the various rivets. For the case of a steel main plate, aluminum cover-plates, and steel rivets, the calculated values indicate a more serious condition of over-load on the outer rivet than was measured experimentally.

Specimen No. 3 failed by shearing the rivets at a load of 151 500 lb, which corresponds to the calculated strength of the joint, calculated as the total shear strength of all the rivets. This fact suggests that at the breaking load each rivet was carrying an equal share of the load.

The frictional resistance of a riveted joint, as a factor in its behavior, is frequently given considerably more importance than it merits. According to the theory of static frictional resistance, load on the joint is resisted by frictional forces between the plates, and is accompanied by no relative movement of the adjacent faces of the plates. Mr. Hrennikoff discusses the action of the static friction in a joint having more than two rivets in a longitudinal row. His conclusion is correct that "a method of design based on allowing a uniform value for each rivet, working in friction [as is done in designing for shear], is wrong." However, the statement that only the outer rivets are effective in static friction, the intermediate rivets performing no work, is not entirely true. To maintain static friction, it is essential that there be no relative movement of the adjacent faces of the plates. This does not mean that the length of the plate, A_1B_1, must be the same as that of the plate, A_2B_2 (Fig. 1(*c*)). It is entirely possible for the two adjacent faces of the plates between A and B to remain the same length and yet for the shear detrusions to be distributed throughout the thickness of the plates so as to produce average changes of length that are different for the two plates. In the case of the lap-joint shown in Fig. 1(*c*), this phenomenon would be accompanied by bending of the plates, which is just what occurs when such a joint is subjected to a tensile load. It is possible, therefore, for the inner rivets to function in static friction before slip has occurred at the outer rivets. It is true that the percentage of the load that would be resisted by static friction of the inner rivets would be relatively small and, for practical purposes, the assumption that the outer rivets carry all the load (in static friction) is probably not far wrong.

Tests made on Specimen No. 2, Table 5 (which was fabricated with hot-driven steel rivets) revealed slipping in the joint even at very low loads. The results of these tests are shown in Fig. 13. Measurements were made of the change in length of the cover-plates between the first rivets on either side of the splice and over the gap between the two main plates. If the load were supported entirely by friction in the joint, the change in distance measured over the gap should be about the same as that measured in the

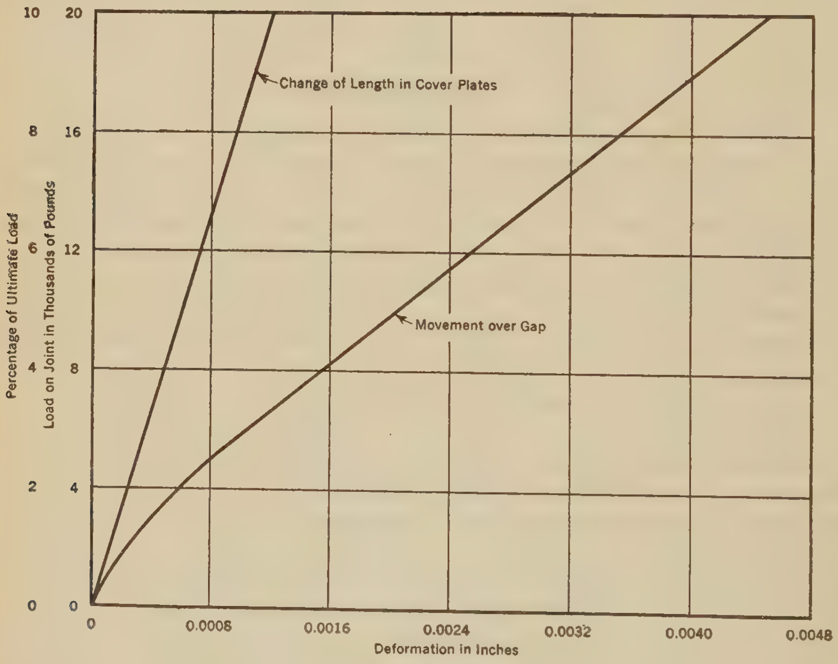

FIG. 13

cover-plates. Fig. 13 shows that the change in distance measured over the gap was relatively greater for extremely low loads, indicating a slip between the plates with the consequent loading of the rivets. Experience has shown that, in general, the friction between aluminum and aluminum, and between aluminum and steel (which are the conditions in Specimen No. 2, Table 5) is greater than the friction developed between steel and steel under the same circumstances. The frictional resistance in Specimen No. 2, therefore, was probably greater than would have been encountered in a similar all-steel joint.

From the results of the investigation, the following conclusions were drawn:

1.—At the working load, the load on a riveted joint is not equally distributed among the rivets in a longitudinal row, as is customarily assumed in design. In a double-strap butt-joint having cover-plates of one-half the thickness of the main plates, the end rivets on either half of the joint carry the greatest load, when the plates are of the same material. In the case of a steel main plate and aluminum cover-plates the first and second rivets from the splice are most highly stressed.

2.—At the breaking load, each rivet carries an equal share of the load, provided the rivets are the same size and of the same material.

3.—The problem of determining the distribution of the load among the various rivets of a joint such as those tested, can be solved mathematically, by considering the elastic deformations of the plates and assuming that the relative displacement between the plates at a rivet is proportional to the load transmitted by the rivet. The relationship between the relative displacement of the plates and the load on the rivet can best be determined experimentally.

4.—The manner in which the load is distributed among the various rivets in a joint depends on the following factors:

(*a*) The type and physical dimensions of the joint, including the width, thickness of plates, pitch, number, and diameter of rivets.
(*b*) The mechanical properties of the materials of the component parts.
(*c*) Uncertainties introduced by fabrication of the joint.

5.—Slip in the joints occurred at extremely low loads, indicating that the static frictional resistance of joints similar to those tested, is of minor importance in a consideration of its behavior under load.

While the unequal distribution of load on the rivets of a riveted joint is worthy of consideration, in the design of many structures with a relatively large factor of safety based on the ultimate strength of the structure, this consideration is not of primary importance. Since at the failure of a joint, the load is probably equally distributed among the rivets, such an assumption for design purposes seems rational. In certain special cases, however, such as riveted joints in machine parts, or structures that are subjected to a great number of repetitions or reversals of stress, the overload on the outer rivets may be of serious consequence, producing fatigue failures in the rivets. A rational design under such conditions should consider the unequal distribution of the load among the various rivets.

DONALD E. LARSON,[15] JUN. AM. SOC. C. E. (by letter).—An interesting analysis of the deformations and stresses in riveted joints is presented in this paper. Such an analysis reveals the fact that all the rivets in certain types of joints cannot possibly be stressed equally at working loads. In spite of this fact, nearly all riveted joints are designed in accordance with the assumption that the rivets are stressed alike, and this leads to a simple and convenient method of design. No design procedure, however, can be justified on the basis of simplicity if it does not provide adequately for the stresses to which the member is to be subjected. The real justification for proportioning joints on the basis of equally stressed rivets lies in the probability that, before failure occurs, the overstressed rivets will yield and thus will effect a more uniform distribution of load. It follows that the theoretical ultimate

FIG. 14.—STANDARD TYPES OF BUTT-JOINTS

strength of a joint designed on the basis of equally stressed rivets can only be attained when the rivets are made from a ductile material. If they were made of a material that obeyed Hooke's law up to the point of failure, as some materials do, it would be necessary to design all joints by some method similar to that outlined by the author. This design procedure would result in the selection of types of joints differing radically from those now in common use.

While it seems probable that the assumed condition of equally stressed rivets is actually attained before failure occurs, it is interesting nevertheless to speculate on the distribution of stress at working loads, and it is to be regretted that the author did not extend his study to include the more common types of joints used in the construction of large oil tanks, elevated water tanks, and pressure vessels. Standard butt-joints having three, four, and five rows of rivets are shown in Fig. 14. The rivet pitch shown for each of these joints is that which gives the maximum efficiency for the following assumed conditions: (1) All the rivets are equally stressed; (2) the effective diameter of each rivet is equal to the nominal diameter plus $\frac{1}{16}$ in.; (3) the value of the plate in tension = 1.0; (4) the value of the rivet material in shear = 0.75; and (5) the value of the rivet material in bearing = 1.5. Theoretically, the strength of the net section of the main plate is equal to the shearing strength of the rivets for each joint.

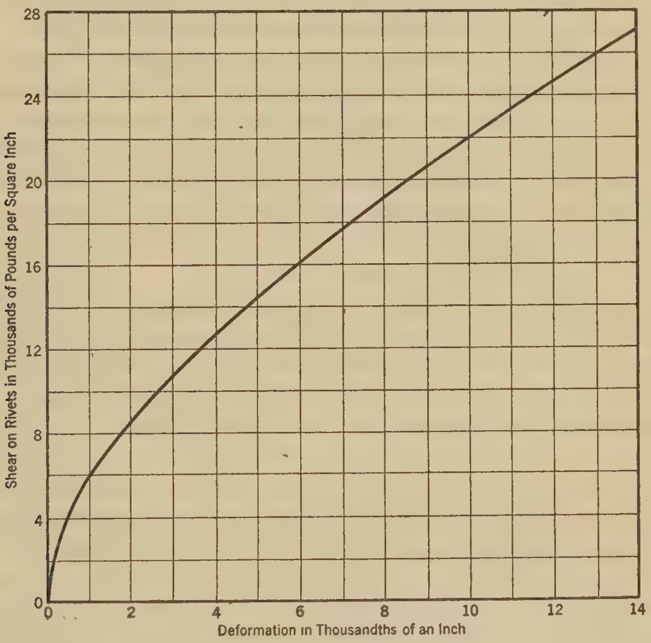

FIG. 15

In making an analysis of these joints to determine the stresses on the various rivets at working loads, the algebraic method used by the author was abandoned in favor of a method of successive approximation for the following reasons: (*a*) The algebraic expressions for the deformations in joints of this type are more or less cumbersome; and (*b*) the relation between the shear on a rivet and the deformation of the rivet is a variable quantity and is not a constant as assumed by the author. This relation between the unit shear and deformation is shown by the curve in Fig. 15. Although this curve is based on experimental data[16] obtained by measuring the slip in joints containing $\frac{5}{8}$-in. rivets, it has been used for determining the deformations of the larger rivets in the joints shown in Fig. 14, because of the lack of actual experimental data for these sizes. The rivet stresses are preferably determined as follows:

Step 1.—Apply a force to the main plate of the joint and, assuming that this force is equally distributed among the rivets, compute the tensile stresses in the main plate and in each of the butt-straps between successive rows of rivets.

Step 2.—Using stresses from Step 1 compute the elongation of the main plate and of each of the butt-straps between successive rows of rivets; then, from these elongations, compute the amount that each rivet must deform to preserve continuity.

Step 3.—Using rivet deformations from Step 2, determine from Fig. 15 the unit shear that must act on each rivet to produce the given deformation; and from these unit shears compute the total shear on each rivet.

Step 4.—Using the new set of rivet shears from Step 3, recompute the tensile stresses in the main plate and in each of the butt-straps between successive rows of rivets; then using this new set of stresses repeat Steps 2, 3, and 4 until the same results are obtained twice successively. When this condition is reached the total force acting on the joint is distributed among the rivets in such a manner that static equilibrium is maintained and the deformations of the rivets, the main plate, and the butt-straps are such that continuity is preserved in all parts of the joint.

The procedure outlined can be hastened considerably by guessing at the probable distribution of the force applied to the main plate in Step 1 instead of assuming that it is equally distributed among the rivets. Of course, the results obtained are exactly the same as those obtained by writing equations for the deformations and solving them simultaneously to determine the unknowns.

To each of the joints shown in Fig. 14, a force that will produce a unit shearing stress of 10 000 lb per sq in. on each of the rivets, if equally distributed among them as assumed in the design, has been applied. The actual distribution has then been computed by the four steps outlined, and the results are shown in Table 6. Each part of the table, 6(*a*), 6(*b*), and 6(*c*), shows the total shear acting on one rivet in each row, the unit shear on that rivet, and the percentage by which this unit shear differs from the 10 000-lb unit shear for which the rivet was designed. This analysis shows that for each of the three joints the rivets in the outer row are the ones most highly stressed. The stress on the outer rivet of the three-row joint is 14% greater than that for which it was designed, whereas the outer rivet of the four-row joint is 34% overstressed, and that of the five-row joint is 42% overstressed. The percentage of over-stress on the rivets in the outer row increases as the number of rows of rivets is increased.

---

[16] See Fig. 39 in "Tests of Joints in Wide Plates," *Bulletin No. 239*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

Although it is evident from the foregoing analysis that the rivets in the outer rows of standard butt-joints are greatly overstressed at working loads, it can be stated definitely that this condition does not seriously reduce the ultimate strength of the joint, providing the rivets are made of a ductile material. This statement is based on experimental data obtained from tests[17] of joints in plates having a width of 6 ft. Two three-row joints having the exact dimensions shown in Fig. 14(*a*) and Fig. 14(*b*) developed an average ultimate strength equal to 98% of the theoretical strength computed from the control specimens, on the assumption that all the rivets were equally stressed. Both these test joints failed by tearing of the main plate and not by shearing of the rivets. Similarly, four, four-row joints having the dimensions shown in Fig. 14(*c*) and Fig. 14 (*d*) developed an average ultimate strength equal to 92.5% of the theoretical strength determined in the same manner. Two of these joints failed by shearing of the rivets and the other two failed by tearing of the main plate. These tests indicate that the actual ultimate strength attained by the joints are fairly consistent with the theoretical strengths computed by the usual method in which the rivets are assumed to be equally stressed. Although it would be better design practice to proportion riveted joints in such a manner that all rivets would be equally stressed at working loads as well as at the point of failure, the tests cited herein seem

to indicate that the usual method of design provides joints having the required ultimate strength, and, for this reason it does not seem likely that the present design method will be replaced by more exact methods in the near future.

A. E. R. DE JONGE,[18] M. AM. SOC. C. E. (by letter).—The problem dealt with by the author is not a new one. When such an old problem is discussed again one expects that either some new results are found, or some new and simpler method of dealing with it is established. The writer proposes to discuss how Mr. Hrennikoff's paper measures up to these two standards.

At an early date it was realized that the distribution of the load on a riveted joint over the various rivets is not uniform. This seems to have been clearly expressed for the first time as far back as 1867 by J. W. Schwedler,[19] in Germany, who unfortunately did not follow up this problem. Attention was once more drawn to this subject in 1881 by the late W. C. Unwin,[19a] Hon. M. Am. Soc. C. E., in England, and again, in 1884, by Th. Landsberg,[20] in Germany.

As far as the writer is aware, the first to state definitely that the outer rivets of lap-joints and the outermost and innermost rivets of double-butt strap joints transmit a greater part of the load than the intermediate rivets, was J. T. Milton,[21] in England (1885).

During some tests made by G. Lanza,[22] in 1887, at the Watertown, N. Y., Arsenal, of the United States Ordnance Department, an attempt was made to find the distribution of load on the various rivets from the uneven elongation of the rivet holes.

In 1892, C. Bach,[23] in Germany, showed from tests that the resistance of the rivets in the various rows was not the same, due to the unequal distribution of the force transmitted by the joint. In England, C. E. Stromeyer,[24] discussed, in 1893, the problem of the partition of load on the various rows of rivets, citing Milton's experiments.[21]

The same subject was discussed in the United States in 1902 by W. H. Boughton,[25] Assoc. M. Am. Soc. C. E., who investigated the question as to whether or not, in the light of the knowledge of an unequal distribution of the load over the various rivets, the usual rivet connections required changing. His answer was that no changes were required.

A discussion was started in the United States in 1904 by an anonymous letter in *Engineering News*,[26] on the same subject, in the course of which the Editor drew attention to the lack of systematic experiments on the subject.

[26] *Engineering News*, June 9, 1904, pp. 542 *et seq.*

The first, to the writer's knowledge, to undertake a rigid mathematical analysis of the subject was Ivan Arnovļevič,[27] who in Austria, in 1908 and 1909, derived general formulas for the load transmitted by each rivet of a double-butt strap joint. While it is true that Arnovlevič only treated of butt-joints, his method is quite general and is equally applicable to lap-joints. He showed that the two outermost and the innermost rivets of each half of a butt-joint transmit most of the load, while the intermediate rivets transmit only a very small part of it. He further showed that on account of this distribution more than five rivets in line are useless, since the additional rivets transmit insignificant fractions of the load only. In addition, he dealt with bracket-plate and chord girder plate connections. In his conclusions, Arnovļevič definitely states the laws as revealed by his investigation and gives finally the following recommendations:

1.—The rivet pitch in the direction of the bar should be as small as possible.

2.—Fewer rivets of a large diameter are more advantageous than more rivets of a small diameter.

3.—More than five rivets in a line parallel to the axis of the bar are useless.

4.—Excessively strong butt straps impair the strength of the joint.

5.—The connection of truss members by means of gusset-plates is more advantageous than their connection to the web-plates of chord girders.

His solution is very elegant and quite general. It allows of the checking of the formulas by the determination of the "rivet factor" from experimental results, and thus his investigation opened the way for a rational treatment of riveted joints in general, which, however, was unfortunately never attempted.

Tests made in 1911 by Max Rudeloff,[28] in Germany, and reported on again later by F. Kögler[29] showed the unequal distribution of the load by the unequal elongation of the holes.

William H. Burr, M. Am. Soc. C. E., in the United States, likewise discussed[30] this problem. (See the Sixth (1904) and Seventh (1915) Editions of Professor Burr's book.)

In 1916, R. N. Blackburn[31] published in the United States a study on unsymmetrical riveted boiler joints and showed that these joints (lap-joints and butt-joints with a wider inner than outer butt strap) are less efficient than symmetrical double-butt strap joints due to the unequal distribution of the forces and stresses.

In 1916, Professor Cyril Batho,[32] of McGill University, Montreal, Que., Canada, made an exceedingly careful investigation of the partition of load in riveted joints and derived, by means of the principle of least work, theoretical formulas for the load transmitted by the various rivets. He checked his theoretical results by experiments in which the strain at various points of the joints was measured by means of very sensitive strain-gauges. The result of these experiments proved to be in good agreement with his theory. He thus proved that a riveted joint may be considered as a statically indeterminate structure and that the loads carried by each rivet may be obtained by the principle of least work in terms of a quantity, K, which depends on the manner in which the work is stored in the joint. He determined this coefficient, K, both theoretically and experimentally, finding fair agreement. He also considered the influence of an unequal distribution of the stresses in the plates, both transversely and longitudinally, the unequal distribution of the load between the two cover-plates, and the influence of the difference of the modulus of elasticity of the cover-plates to that of the main plate, as well as other types of connections.

Professor Batho's results, although obtained in a totally different way, agree well with those of Arnovlevič.[27] Professor Batho also showed how to calculate the distribution of load in lap-joints and thus goes a step further than Arnovlevič. He covered, therefore, a great part of the field of riveted joints as used in structural engineering.

In Austria, Paul Fillunger[33] again treated of this subject in 1919, but considered the rivets as mere points being completely rigid while the plates only were subject to deformation. His results are somewhat similar to those of Arnovlevič[27] and Batho.[32]

In 1920, James Montgomerie,[34] in England, made a number of very careful experiments for the Committee of Lloyds Register, in order to ascertain the elastic behavior of riveted joints. He investigated lap-joints only, and the measurements with a very sensitive strain-gauge confirmed the fact that the distribution of both load and stresses was nowhere uniform throughout any of the joints.

In the same year, D. Rühl,[35] in Germany, made very careful measurements of the strains in a plate around the rivet holes and showed that the elongation is little influenced by the uneven distribution of stresses, a fact already shown by Batho.[32]

In 1920, Cl. Findeisen,[36] in Germany, also made experiments on the distribution of the stresses in the cover-plates of butt-jointed flat bars, using cylindrical well-fitting bolts as connectors. His investigations and careful measurements are of value in so far as they permit of the determination of the distribution of load over the various pins and the checking of certain constants, as explained later.

John S. Watts,[37] in the United States, pointed out in 1921 again, as did Mr. Blackburn,[31] that unsymmetrical double-butt strap joints with wider inner than outer butt strap (as used in boilers) are less efficient than symmetrical double-butt strap joints due to the better distribution of the load in the latter.

[37] *Boiler Maker,* Vol. 21 (October, 1921), pp. 278-279.

In 1922, A. Hertwig,[38] in Germany, proposed using the deflection of the rivet heads as a means of determining the distribution of load on the various rivets.

R. Maillard,[39] in Switzerland, dealt in 1923 with the same problem and recommended short joints, rather broader than those used at present, or joints with plates tapered or stepped in the measure in which the forces transmitted decrease, or increase, respectively.

James Montgomerie,[40] in England, supplemented in 1923 his former experiments for Lloyds Committee[34] by tests on lap-joints of heavier plates and larger rivet diameters. His results were similar to those obtained by him for his first series of experiments.

In 1923, Friedrich Bleich[41] published in Germany an investigation on the distribution of the stresses in a bar of rectangular cross-section. His study is remarkable in that it is not based, as were all the others, on the usual simplified Navier theory of stress distribution, but on the much more general theory of elasticity for a two-dimensional state of stress, a state to which riveted joints closely conform. He investigated the problem of stress distribution due to local loads, such as are produced by the rivets on a plate, and *vice versa*, and derived, by means of the Airy stress function, formulas for the distribution of the longitudinal stresses in riveted joints.

In the following year (1924) Bleich published another theory.[42] Due to his former study being based on theoretical deductions only, he based his new theory on the work of Arnovļevič,[27] but treated the subject in a more practical manner by introducing for the movement of the plates at the rivets a proportionality factor which he calls the "slip modulus," assuming that the displacements are proportional to the loads transmitted by the rivets. He determined this slip modulus from the experiment by Findeisen[36] for pins, and for rivets from tests by Rudeloff,[23] introducing the value thus directly obtained from experiments, into his formulas. By means of this slip modulus, he found the percentages of the load transmitted by the various rivets, which percentages, however, are nowhere near those determined by either Arnovļevič or Batho,[32] and indicate a much more even distribution of load (his values being only a small percentage greater than those determined from the theory of the uniform load distribution). The slip modulus is the reciprocal value of Mr. Hrennikoff's constant, k. Thus, Bleich has already done what the author now recommends in his paper, in that he actually determined the all important constant, k, from experimental data, in order to arrive at more correct results.

The Chief Engineer for the Swiss Association of Boiler Proprietors, E. Höhn,[43] carried out in Switzerland, in 1925, an exceedingly careful series of experiments on the behavior of riveted joints. Höhn measured the relative displacements between the bars and butt straps of double-butt strap joints for thin as well as for thick plates at various points of the joint. The stress distribution obtained therefrom was found to be nowhere uniform either in the transverse or longitudinal direction of the bar. The strain curves plotted by Mr. Hrennikoff are somewhat similar to those plotted by Höhn, but Höhn's curves are by no means straight lines. Höhn discussed his important results at great length and gave also rules regarding the lay-out of riveted joints.

A further remarkable series of experiments was carried out in 1926 by Commander E. L. Gayhart, U. S. N. Some of the results were published by him and Professor William Hovgaard.[44] This series of experiments is of the utmost importance, not only because they were carried out with exceptionally large double-butt strap joints, but also on account of the great accuracy of the measurements. The results confirmed the findings of the previous experimenters and investigators in that they show for all stages of loading (just as in Batho's case[32]) that the outer rivets carry by far the greater amount of load, although the inner rivets take an increasing share of it as the load increases. Unfortunately, Commander Gayhart, contrary to Batho, has not published the necessary data of the strain measurement which would permit of a check. It is, therefore, not possible to derive, from the results of Commander Gayhart, the value of the constant, *k*, of Mr. Hrennikoff.

A. Hertwig and H. Petermann[45] in Germany attempted, in 1929, to solve the same problem by the method suggested by Hertwig,[38] which consisted in measuring, by optical means, the angular deflections of the ends of the rivet heads due to the bending of the rivets. This attempt was unsuccessful, however, and the experimenters substituted well fitting pins for the rivets just as were used by Rühl[35] and Findeisen.[36] The results thus obtained again showed that the distribution of the load is not uniform. As a check the second of the investigators derived general formulas for this case.

How important the determination of the load distribution in riveted joints is held in England, may be seen from the First Report of the Steel Structure Research Committee of the Department of Scientific and Industrial Research of the British Government,[46] published in 1931. Professor Batho's method[32] of calculating the load distribution in riveted joints was incorporated in this report.

Otto Graf in Germany published[47] in 1931 a booklet in which he reported on experiments with riveted and welded bars of various steels under high sustained loads (long-time strength tests) and under fluctuating tension loads. He found that the bearing stresses at the holes changed the state of stress distribution in the main bars so that fracture under repeated loading took place ahead of the outermost rivets of the joint and not at the weakest cross-section in the first rivet row as in ordinary tension tests. He also carried out investigations into the load distribution under fluctuating tensile loads. While these tests were not completed at the time the booklet was published, the results obtained to that time indicated that the distribution of load under often repeated load variations is much more uniform than was to be expected from the older investigations with pins (obviously, Findeisen's investigation[36] and those by Hertwig and Petermann[45] are meant), which latter investigations were carried out as ordinary tensile tests. The increase in temperature of the rivet heads in joints with three rivets in line differed only slightly, thus showing a more even distribution under varying loads.

[47] "Dauerfestigkeit von Stählen mit Walzhaut ohne und mit Bohrung von Niet-und Schweissverbindungen," by O. Graf, pub. by the V. D. I.-Verlag, Berlin, 1931.

The results of these tests were published[48] in 1932. The author discussed the importance of the frictional resistance and referred to Wellinger's "Dissertation"[49] in which the means of obtaining the highest possible clamping forces with rivets were described. Not until the frictional resistance is overcome, do the rivets touch the walls of the rivet holes.

Graf discusses here in greater detail than in his booklet the fact that, under the influence of friction and repeated loading, fracture occurred in the plate slightly ahead of the first rivet. He also showed that the relative displacements of the bars are permanent to a large extent, that a varying load is distributed more evenly than a mere statical load, and that the total deformations were greater than for ordinary tensile tests, the permanent part having increased while the elastic part was altered but slightly.

By investigating the deformation and final destruction of rivets under often repeated loads, Graf made a further considerable step forward. The extent to which the forces in the joint are transmitted by the various rivets coming into direct contact with the wall of the holes, after overcoming the frictional resistance, can be derived from the deformation of the rivets. These were studied by R. Wörnle[49] who, under Graf's guidance, measured the deflection by means of small pins having three collars and being fitted tightly into holes drilled longitudinally through the rivets. The bending of these pins was measured by means of mirrors, and the load transmitted by each rivet was determined therefrom. In this way Graf found that in riveted joints with high rivet clamping forces a very much smaller part of the load is transmitted by the direct action of the rivets than is obtained from the usual calculations which neglect friction. Further, the differences in the load transmitted, under the condition of Graf's experiments, by three or more rivets in line, were less than those in the case where no frictional resistance is assumed to be present.

Attention should further be drawn here to the painstaking investigations of Th. Wyss,[50] in Germany, who in 1923 derived from innumerable strain measurements the distribution of stress in riveted connections, for example, in the gusset-plates connecting members to a chord girder; and, further, to the investigations of Findeisen,[51] in Germany, and Stefan Gállik,[52] in Austria, both published in 1928, who determined the bearing pressure between rivets and plates.

After thus having given a bird's-eye view of the most important research carried out prior to the publication of Mr. Hrennikoff's paper, and after having clearly shown that this problem is not a new one, it is pertinent to investigate the second question, as to whether Mr. Hrennikoff's paper brings a new or simpler method for the determination of the load distribution.

The title of the author's paper leads one to believe that he intends to investigate the work of riveted joints, that is, the storage of energy in riveted joints and the behavior of the joint during such storing of energy; but, in actual fact, all he undertakes is an investigation into the static distribution of load over the rivets and, therefore, it would be more appropriate if he had referred to "the behavior of riveted joints" or "the load distribution in riveted joints."

Mr. Hrennikoff has chosen for his analysis a "logical" rather than a rigid mathematical treatment. In general, he pictures the phenomena occurring in a riveted joint correctly. It is difficult, however, to agree with his statement that "designing on the basis of friction seems to be quite correct in the case of only one rivet in a longitudinal row * * *." (Mr. Hrennikoff uses "longitudinal row" instead of the accepted terminology which designates rivets in the direction of the transmitted force as rivets "in line" and those transverse to it as "rivets in rows" or "rivet rows"). Even if there were but one rivet, slip at the faying surfaces must occur, because the force, which is transmitted by the rivet due to friction, at the rivet heads and between the plates, is not transmitted at one single point only, but is spread over a fairly wide area. Therefore, it is gradually transmitted from one plate to the adjoining one, thus causing in both plates elongations and distortions which differ according to the magnitude of the force that has already been transmitted up to the point under consideration.

His further statement that "it is reasonable to assume that the other part, X_{AS}, of the total force, X_A, developed by the rivet (that due to shear), is proportional to the slip of plates at Point *A*," forms the basis of his investigation and, therefore, should be given due prominence. His assumption, however, is no more than a first approximation since the plates do not deform in the longitudinal direction only, but also in the transverse direction, particularly around the rivet holes. On account of this deformation the slip changes over a wide area, and it is impossible to state, the slip of which point should be regarded as "the slip." Thus, Mr. Hrennikoff can undoubtedly refer to the "mean slip" only and thus arrive also at a first approximation only. Arnovļevič[27] and Bleich,[41] who have done exactly the same, have not neglected, however, to state so expressly. Furthermore, the author has completely neglected friction.

Since it is doubtful whether a rigid analysis of the entire problem by means of the theory of elasticity will ever be possible, the writer agrees that some such simplifying assumption is necessary; but a suitable factor should be included allowing for the adaptation of the results of the mathematical analysis to the results from experiments. Mr. Hrennikoff, like Arnovļevič and Bleich, has incorporated this factor in his rivet factor, *k*.

The derivation of his formulas follows the "logic of Part I," but it must be stated that his "logical" method rather clouds the issue. A plain mathematical analysis accompanied by a simple diagram showing the deformations would have obviated a large part of the complicated description and would have been more to the point in that the main formulas could have been derived directly and would have led to general formulas instead of to specific ones. Besides, it would also have obviated the omission of the deductions for cases having more than three rivets and for butt-joints.

If one analyzes mathematically what lies behind the long explanations, one finds that Mr. Hrennikoff compares the respective motions of the two plates at the various rivets with one another. For this purpose he chooses as "a fixed point in space" the center line of the rivet at the extreme right-hand end of the upper plate; but the lower plate at this very point still moves to the right for a distance $-l$.

All this would have been unnecessary if he had drawn a diagram, such as Fig. 16. It would have been evident, therefrom, that the only requirement is to equate the distances of the respective center lines from any rivet head at one plate to the next following rivet head at the other plate, using one time the deformations of one plate and rivet and the other time those of the other plate and rivet. This, after all, is exactly what Mr. Hrennikoff has done without expressly stating it. In this manner, he would have obtained the following system of equations, using the notations of Fig. 16:

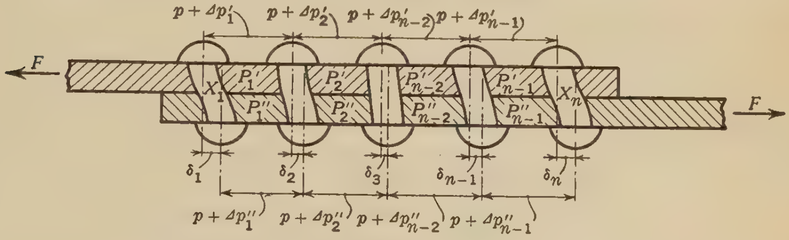

FIG 16

$$p + \Delta p'_1 + \delta_2 = p + \Delta p''_1 + \delta_1 \qquad \text{(28)}$$

or,

$$\left.\begin{array}{l} \Delta p'_1 + \delta_2 = \Delta p''_1 + \delta_1 \\ \Delta p'_2 + \delta_3 = \Delta p''_2 + \delta_2 \\ \Delta p'_3 + \delta_4 = \Delta p''_3 + \delta_3 \\ \cdots\cdots\cdots\cdots \\ \Delta p'_{n-1} + \delta_n = \Delta p''_{n-1} + \delta_{n-1} \end{array}\right\} \qquad \text{(29)}$$

The respective elongations, $\Delta p'_1$, $\Delta p''_1$, etc., as well as the deflections of the rivets, $\delta_1, \delta_2, \ldots, \delta_n$, can then be expressed by the forces acting in the various plate sections and by the forces transmitted by the various rivets. If the forces transmitted by the various rivets are $X_1, X_2, X_3, \ldots\ldots, X_n$, and the forces acting in the plates between rivets, m and $m + 1$, are in the upper plate, P'_m, and in the lower plate, P''_m, then there exists the following system of equations (designating the load on the joint by F):

$$\left.\begin{array}{l} F - P'_1 = X_1 \\ P'_1 - P'_2 = X_2 \\ P'_2 - P'_3 = X_3 \\ \dots\dots\dots\dots\dots \\ P_{n-1} = X_n \end{array}\right\} \dots\dots\dots\dots\dots\dots\dots\dots (30)$$

and, by addition,

$$X_1 + X_2 + \dots + X_n = F \dots\dots\dots\dots\dots\dots\dots\dots (31)$$

It should be emphasized that Equation (31) is not an independent one. Furthermore,

$$\left.\begin{array}{l} P'_1 + P''_1 = F \\ P'_2 + P''_2 = F \\ \dots\dots\dots\dots\dots \\ P'_{n-1} + P''_{n-1} = F \end{array}\right\} \dots\dots\dots\dots\dots\dots\dots\dots (32)$$

Since,

$$\left.\begin{array}{l} \Delta p'_1 = \dfrac{P'_1 p}{E w t_1}; \ \Delta p''_1 = \dfrac{P''_1 p}{E w t_2} \\ \Delta p'_2 = \dfrac{P'_2 p}{E w t_1}; \ \Delta p''_2 = \dfrac{P''_2 p}{E w t_2} \\ \dots\dots\dots\dots\dots\dots\dots\dots\dots \\ \Delta p'_{n-1} = \dfrac{P'_{n-1} p}{E w t_1}; \ \Delta p''_{n-1} = \dfrac{P''_{n-1} p}{E w t_2} \end{array}\right\} \dots\dots\dots\dots (33)$$

and, since,

$$\left.\begin{array}{l} \delta_1 = kX_1 \\ \delta_2 = kX_2 \\ \dots\dots\dots \\ \delta_n = kX_n \end{array}\right\} \dots\dots\dots\dots\dots\dots\dots\dots (34)$$

there are six systems of equations, or $6n$-4 equations in all, for the $6n$-4 unknowns—from which the $6n$-4 unknowns (and, consequently, the unknown rivet forces, X_1, X_2, ..., X_n), can be determined. In this way general formulas may be derived which yield for the cases dealt with by Mr. Hrennikoff exactly the same formulas as found by him. It would be very interesting to know, exactly how he has derived the formulas for more than three rivets, because he gives the derivation of this simplest case only; but by whatever mathematical or "logical" process he has arrived at these solutions, the general method is exactly the same as that used by both Arnovlevič[27] and Bleich.[41]

The most important point in the entire evaluation of the formulas, however, is the determination of the factor, *k*. It is creditable that Mr. Hrennikoff, like Arnovļevič, has attempted to determine this factor analytically. Unfortunately, Mr. Hrennikoff has not given this derivation so that it is impossible to determine the accuracy of his results. Mr. Hrennikoff obviously feels, and rightly so, that this determination can only be regarded as a first step and advocates the determination of *k* by experiment. Bleich has previously done this by attempting to determine this value, or rather its reciprocal value, from Rudeloff's experiments.[26] Obviously, Bleich did not know of Batho's anaylsis and experimental data,[32] because he could have used these to check his value for the "slip modulus." Thus, Bleich went a step further than Mr. Hrennikoff, and the latter's results can be of no more than academic interest.

The writer would like to give Mr. Hrennikoff credit for one advance that his analysis has established. He has resolved the cross-sectional area of the plates and cover-plates into width and thickness. Thus, he is able to get, for the same plate width, from his formulas directly the rivet coefficient for any plate thickness while the formulas of his predecessors do not allow of this directly, requiring a further though short calculation.

In valuing Mr. Hrennikoff's paper it must be pointed out that he has given a solution for a limited number of cases only; that is, for lap-joints containing up to six rivets and for butt-joints containing up to three rivets. His predecessors, however, have given general formulas which they evaluated for various cases, for double-butt strap joints up to six rivets. If one further compares Mr. Hrennikoff's four conclusions with those given by his predecessors, it is difficult to find anything new in them.

It may not be amiss to state further, that Mr. Hrennikoff has not taken into consideration the bending in lap-joints due to the moment created by the plates not lying in one plane. This changes the distribution of forces materially on account of the bending it induces in the rivets in addition to that present if the plates were not subjected to this bending moment.

At the beginning of Part I, Mr. Hrennikoff makes the statement that riveted joints "are not well understood." To this very true statement the writer would like to add that "the literature on riveted joints" does not seem to be well known, either. This has been the reason why he has prepared[53] a rather comprehensive "Bibliography on Riveted Joints." He would recommend its careful study to all who intend to carry out any experimental or theoretical work on riveted joints. It is simply amazing how much has been duplicated, how many immensely costly experiments have been carried out, the readings and data of which have never been published and, therefore, cannot be evaluated to the limit of their usefulness. Any progress in riveted joints can only come from a careful study of all the results obtained thus far and from outlining further tests with the idea of checking up experimentally the factors involved, a procedure which has also been recommended by Mr. Hrennikoff.

---

[53] "Riveted Joints: A Historical Survey of Their Development, with a Bibliography and Abstracts from the Literature," by A. E. R. de Jonge, *Research Publications*, A. S. M. E. (1934).

The writer would like to take this opportunity to sound a note of warning with regard to the calculation of riveted joints based on insufficient assumptions. As almost no structure is subjected to a steady direct load, but rather always to variations in load, these latter should receive due attention. Further, it is useless to try building up a rational theory of riveted joints without taking the frictional resistance of the joint into consideration. Only by the co-ordination of all factors having a bearing on the resistance of riveted joints can a theory be arrived at which will describe the behavior of riveted joints more or less correctly. Graf's investigations[47] [48] form a first step toward this end. If Mr. Hrennikoff's paper will have the effect of starting a new movement in the direction outlined by the writer, the latter can do no better than to thank the author heartily for his paper.

A. Hrennikoff,[54] Esq. (by letter).—The response given this paper and the points of interest and importance brought out in the course of the discussion are gratifying. In answering these points it will be necessary to reexamine some of the original statements in the light of new information.

The main claim was that, in a riveted lap-joint or butt-joint with more than two rivets in a longitudinal row, under working conditions, distribution of the load among the rivets would be non-uniform, the outer rivets taking the greater part of the stress. Most of the discussers accept this assertion, and some of them mention experimental evidence in its support. However, correct theoretical estimation of this inequality and of the relative values of factors instrumental in producing it is almost impossible. The difficulty lies in the uncertainty of the relation between the slip of the plates at the rivet and the force developed by it. In a joint under a steady direct load this relation is determined mostly by the following three factors: The resistance of rivet in shear and bearing; the friction force; and the clearance around the hole caused by cooling of the rivet. Diversity of conditions and methods of fabrication are chiefly responsible for the uncertainty in relative importance of these factors in any particular joint; therefore, the force-slip curves assume a variety of shapes.

Messrs. Hill and Holt, referring to their experiments with double-strap butt-joints of aluminum and steel plates, state that slip begins very early, that friction is comparatively unimportant, and that the force-slip curve does not depart from a straight line passing through the origin sufficiently to invalidate the results based on the straight-line relation.

The force-slip curve to which Mr. Larson refers (Fig. 15) is not straight. It begins vertically at the origin, indicating that very small loads are resisted by the rivet almost without any deformation, and then gradually diminishes its slope with the horizontal.

In the paper[55] from which Fig. 15 was taken, several other force-slip curves of entirely different character are given, of which Fig. 17 is typical. This curve has a long, nearly vertical section, which changes its slope rather sharply into one not far from horizontal. Although the ordinates of this curve represent the average shear stresses for all four rivets in the joint, and not for the rivet under consideration, a moment of thought will convince one that if it was possible to reduce the ordinates to shear stresses of the rivet in question, the general shape of the curve would still be preserved.

---

[54] Instr., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

[55] See Figs. 42, 45, and 48, in "Tests of Joints in Wide Plates," *Bulletin No. 239*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

These are the three types of the force-slip curves that have come to the writer's notice, and he believes that most of the rivets in riveted joints, if tested, would exhibit one of these shapes or some intermediate form. (It may be mentioned, by the way, that Mr. Roop's Fig. 12, representing a relation between force and over-all deformation of the joint, cannot be used here, because it is constructed on an entirely different basis.) The formulas in the paper are based on the first type, a straight line through the origin, indicating the absence of both friction force and clearance around the rivet, although the rivet deformation may not necessarily be entirely elastic. This is an extreme case, but an approach to it seems possible under certain conditions, as is illustrated by the discussion of Messrs. Hill and Holt, who have found fair agreement between the experimental and the theoretical (based on an experimental value of the rivet coefficient) stress distributions among the rivets, as shown in Table 5.

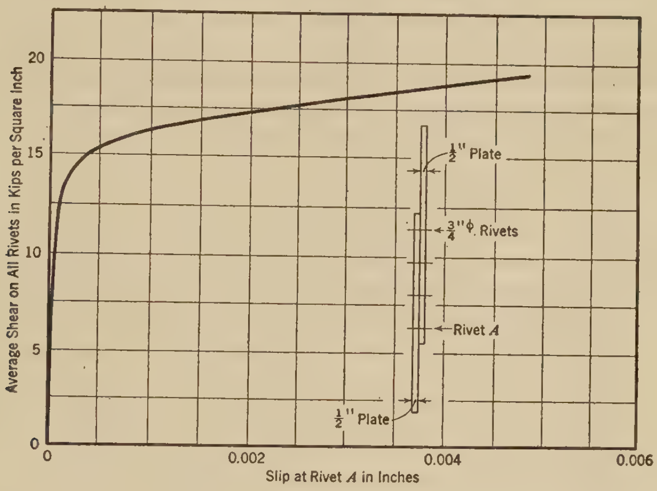

FIG. 17.

When the force-slip curve deviates considerably from a straight line these formulas naturally do not apply; yet, if the expected force-slip curve is known, or at least the limits between which it may fluctuate, the distribution of the load among the rivets may nevertheless be obtained theoretically by the excellent method of successive approximations suggested by Mr. Larson. The writer has applied the method to a few examples and has found that successive values of the rivet forces converge rapidly, so that the final results may be obtained after the second or third trial.

An analysis of a joint in which the rivets show the force-slip relation of the type represented in Fig. 15, still indicates an over-stress of the outer rivets. By using the curve of Fig. 17 the result may be different, and it seems appropriate to investigate this case in the light of the discussion presented by Mr. Shearwood, who strikes a rather different note, demonstrating how a friction force of a certain magnitude, combined with sufficient clearance around the rivet will cause equal stress distribution. The ideal stress-slip relation, according to Mr. Shearwood's assumption, seems to be as typified by Fig. 18. The rivet develops a force to the limit of its frictional resistance, almost without any deformation, after which it slips until all the clearance is absorbed, and the rivet shank comes in contact with the plates; then the rivet force increases again, owing to resistance in shear and bearing. The values computed by Mr. Shearwood are only illustrative, of course, but they are fairly representative of results to be expected under average conditions of fabrication. The resemblance which the curve of Fig. 18, from the origin to Point *A*, bears to the experimental curve, Fig. 17, is significant and testifies for the soundness of Mr. Shearwood's arguments. Since in this case a comparatively severe slip of the outside rivets requires no increase in rivet resistance, as long as any clearance is still left, Mr. Shearwood succeeds in demonstrating, by two examples of lap-joint and butt-joint, that if the working load is equal to the sum of the frictional resistances of all the rivets, the distribution of the load among the rivets will be perfectly uniform.

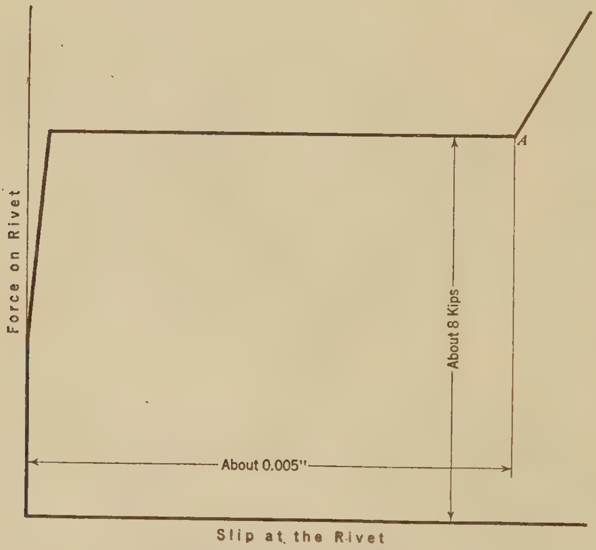

Fig. 18.—Force-Slip Diagram for ⅞-Inch Single-Shear Rivet.

If it happens that the working load is less than the sum of the frictional resistances of all the rivets, a certain number of inner rivets are idle, the remainder exerting forces equal to their frictional resistances. On the other hand, if the working load is greater than the sum of the frictional resistances of the rivets the plates slip one over the other, and the excess of the load is borne almost completely by the extreme outer rivets.

Thus, summarizing the results for various kinds of force-slip relations, an approximate equality of rivet forces under working conditions seems possible only for one type of the force-slip curve (Fig. 17) and for one definite relation between the load and the frictional resistance, over which the designer has no control. For other conditions the working load does not divide equally, and the outer rivets are overstressed.

Referring to the diagrams constructed by Mr. Troelsch in which he compares the results obtained by his weld theory with those of the rivet theory, one would not fail to notice their close agreement. Of course, as Mr. Troelsch explains, this agreement is only natural, since the underlying assumptions of both theories—proportionality between the stress and deformation in weld and rivet—are identical. It is only fair to state that Mr. Troelsch's weld formula,[56] independent as it is of the number of rivets, if they are spaced uniformly, is preferable to the rivet formulas, which increase considerably in complexity as the number of rivets is increased.

Mr. Roop presents an interesting discussion elucidating the behavior of riveted joints under stress. Assuming a continuous connection between the plates, he arrives at a formula for the stress in the plates, σ, which is reducible to Mr. Troelsch's Equation (23).[57]

There is no doubt as to the correctness of Mr. Roop's statement that the clamping effect of a rivet extends over a large area around it; on the other hand, one cannot see any mechanism through the medium of which continuous stress over all the faying surface would assume the intensity at any point proportional to the relative slip at the point. The friction force caused by clamping is, naturally, independent of slip, and is indeed ruinous to a theory based on proportionality between force and deformation. That is why, in developing his formulas, the writer (by assumption) eliminated friction from consideration and left all load to be resisted by the isolated units (the rivets) which presumably may develop forces proportional to deformations. The writer is thus more inclined to prefer the rivet-stress formulas based on continuous connection between the plates because of their greater simplicity for long joints and on their independence of the number of rivets, rather than because of closer conformity to reality.

The assumption of rivets of very small size ("point rivets"), attributed by Mr. Roop to the writer, appears not absolutely necessary, although the finite size of the rivets naturally requires some reduction in the width of the plate, or in the pitch, similar to that suggested by the writer, in order to take account of the rivet hole; and also, as Mr. de Jonge points out, "the slip" at the rivet becomes actually the average slip, since different points in the vicinity of the rivet slip somewhat unequally. Mr. Roop's discussion of the experimental phase of the question presents a valuable addition to his theoretical analysis.

---

[56] See p. 413, Equation (15).

[57] See p. 414.

To Mr. de Jonge is accorded the credit of contributing an extensive bibliography on the subject. No doubt it will be of great value to future investigators, especially to those who are acquainted with German. The writer wishes to thank Mr. de Jonge for calling attention to two assumptions used in the paper, but which were not stated: One concerning the meaning of the word, slip; and the other relating to the effect of disregarding the bending of lap-joints, owing to their eccentricity. (The latter has also been noted by other discussers.)

Mr. de Jonge's way of attacking the problem of stress distribution among the rivets does not appeal to the writer. Introducing admittedly no new method, he uses an excessive number of unknowns; thus, $(6 \times 3 - 4) = 14$ equations would be required for the solution of a three-rivet lap-joint, where the writer uses only two equations. This economy in the number of unknowns is largely due (aside from the assumption of symmetry) to the use of the displacement diagram, Fig. 3, which assists in forming a mental picture of the deformations associated with the stressing of the joint. Answering a question raised by Mr. de Jonge, constructing such a diagram and equating the vertical distances between two of its curves to the slips of respective rivets, form the basis for the solution of other riveted joints.

The writer feels uncertain also as to the possibility of obtaining from Mr. de Jonge's equations a general solution, applicable to any number of rivets, unless such a solution would be so formidable as to be practically unworkable.

The justice of the main criticism advanced by Mr. de Jonge, that neither the subject-matter of the paper nor its method are entirely novel, must be partly conceded in view of the bibliographic data supplied by him; on the other hand, Mr. de Jonge joins the writer in his belief that the riveted joints "are not well understood," and this seems to be sufficient reason for the presentation of the present paper before the Engineering Profession. It is a significant fact in this connection that, according to Mr. de Jonge, only one theoretical investigation on the subject, that by Professor Batho,[32] using a different method, had been published in English previous to this paper.

A brief discussion of Professor Batho's work[58] with the view of co-relating its results with those of the writer seems to be in order. In the theoretical part of his paper, Professor Batho uses the method of least work; and the algebraic expression for the work of deformation of a rivet in terms of the rivet force, X, is assumed to be proportional to KX^2, in which, K is a coefficient determined by experiment, and is constant for all rivets of the joint under a given load. The form of the rivet-work function, quadratic in X, involves a tacit assumption of proportionality between the rivet force and its deformation (which is equal to the slip of the plates). Under these circumstances, the resulting expressions for the rivet forces are exactly equivalent to the expressions derived by the writer.

---

[58] *Journal*, Franklin Inst., Vol. 182 (November, 1916).

In his experimental determination of the factor, K, for the double-strap butt-joints, Professor Batho does not use the force-slip relation for rivets; his method of attack is to measure the strains in cover-plates between different rivets. This enables him to prove that the outer rivets are overstressed, and to find experimentally the actual distribution of the load among the rivets. In conjunction with his theoretical formulas this leads to an experimental value of the coefficient, K, as follows: $K = \frac{F}{100\,A}$, in which, F is the total force on the joint, in kips; and A is the cross-section area of the upset rivet, in square inches. This formula is intended to be applied only to the joints with dimensions used by the investigator.

The fact that F appears in the expression for K seems to contradict the assumed independence of K from the rivet forces, X, the sum of which is equal to F. Probably Professor Batho's result is due to the shape of the actual force-slip curves which in his tests apparently deviated from the tacitly assumed straight lines, in a manner similar to Fig. 15.

The theoretical relation between the writer's rivet factor, k, and the coefficient, K, of Professor Batho, can be proved to be $K = \frac{w\,t_2\,E}{p}\,k$, using the notation of the paper. Since k in Equations (26) and (27) is independent of the load, and K, according to Professor Batho, increases in proportion to the load on the joint, the two can agree only for one particular value of F. This value for some of the joints studied by Professor Batho is nearly equal to the working load; for others, it is considerably greater. Considering his expressions for k merely as first approximations the writer attaches no particular significance to these results, and mentions them only in view of questions raised by Professor Finlay and Mr. de Jonge. However, the fact that there is general agreement between the two investigations, conducted independently, and by different methods, is gratifying.

The writer quite agrees with Messrs Shearwood, Roop, and de Jonge when they state that the behavior of a riveted joint under variable load depends on its entire previous stress history; but he does not attempt to discuss here this phase of the question, limiting himself to a consideration of the action of a steady load and to the task of calling attention to the weaknesses of conventional design, the assumptions of which (using an apt expression by Professor Finlay), "if given sufficient time for their assimilation, tend to be confused with the eternal verities."

STUDY OF STILLING-BASIN DESIGN

By C. Maxwell Stanley,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. E. W. Lane, C. C. Inglis, F. Knapp, and C. Maxwell Stanley.

Synopsis

This paper presents the results of a study, made by means of hydraulic models, to rationalize the design of stilling basins, one of the several devices used for the prevention of scour at the toe of a dam. The relationships between the fundamental factors controlling the action of the stilling basin are carefully compared and, finally, a method of design based upon these relationships is presented.[2]

The stilling basin may be defined broadly as a pool of water held at the toe of a dam by a weir. Five distinct types of stilling-basin action and their characteristics are classified. The experimental data from the tests are studied to determine the relationships of basin length and depth, dam height, and quantity occurring for each of the five types of action. A more complete form of the paper has been placed in Engineering Societies Library, 33 West 39th Street, New York, N. Y., for reference.

Problem of Scour

The prevention of scour at the toe of an over-flow dam is a problem of importance to the designer, and upon its successful solution depends the safety of the dam. Although the solution of the problem is more urgent in dams constructed upon foundations of sand and gravel, which are easily eroded, it must not be overlooked in dams constructed upon seemingly solid

[2] Prepared from a thesis presented to the University of Iowa in partial fulfillment of the requirements for the degree of Master of Science.

rock. Engineering literature contains too many reports of damage from erosion requiring costly repairs, if not resulting in disastrous failures of the dam itself.

A problem of such importance has naturally been studied to a considerable extent, but the theoretical foundation upon which to base an attack is obscure, and little has been done to formulate the basic laws. No general mathematical formula has been developed, which will allow even an approximate solution. As a result, solutions have been largely empirical, based on judgment and past experience. Their insufficiency has been indicated by the many cases of serious erosion, and although there have been notable examples of successful solution, the net result can scarcely be considered satisfactory.

Within recent years, many satisfactory solutions have resulted from model studies, which are to be highly commended and encouraged. The day is not far distant when experiments with models will be a necessary part of the design of every over-flow dam.

Even if a model study may be counted upon to solve a particular problem some rational method of design for protective devices would be extremely welcome. Such a method would be of great value in preliminary designs and estimates even if supplemented later by a model study.

THE STILLING BASIN

For the purposes of this paper, a stilling basin is defined as a pool of water retained below the toe of a dam by a weir, in order to dissipate energy contained in the water overflowing the spillway and thus to prevent serious erosion. The floor of the basin is assumed to be of concrete or other material that will prevent erosion at the toe where the sheet of water impinges. It should be pointed out, however, that natural conditions may create a pool of such dimensions that a weir is unnecessary, and the resulting actions will be similar to that described herein. A stilling basin thus defined may be deep or shallow, long or short. Naturally, the action will not be the same under these varying conditions of length and depth. The different actions fall into five types, each of which has certain characteristics differentiating it from the others, namely: I.—Roller Action; II.—Jump Action; III.—Incomplete Jump Action; IV.—Pool Action; and, V.—Spray Action.

Type I.—Roller Action.—As the swift stream of water coming down the face of the dam enters the pool of water in Fig. 1, it is deflected by the bucket and turned to a general horizontal direction. Friction on the floor and on the water above decreases the velocity and sets up an eddy or roller about a horizontal axis. This roller is full of air bubbles and slopes backward on top, slightly toward the incoming sheet of water. It absorbs and dissipates energy from the incoming sheet. The turbulence is out of the water before it reaches the weir, and the depth over the weir is just sufficient to discharge the incoming quantity. The only energy remaining is that of the static and velocity heads just above the weir, which is small compared to the incoming energy.

Type II.—Jump Action.—In the action of Type II (Fig. 2), the basin is longer than that of Type I, but in proportion to the quantity of water handled is not as deep. The general appearance is that of a hydraulic jump, as the usual indications of the jump are present. The basin is of sufficient length to allow the complete formation of this jump, with the result that all turbulence is out of the water before it reaches the weir, and it flows over smoothly. The remaining energy is that of the static and velocity heads just above the weir.

Type III.—Incomplete Jump Action.—This type of action is that occuring if the weir of Fig. 2 is moved toward the dam. The part toward the dam still gives every indication of being hydraulic-jump action, but the length is not sufficient to allow the complete formation of the jump.

The depth at the weir does not increase appreciably, but the water, instead of flowing smoothly over the weir, shoots in a more or less horizontal direction. The length clearly is too short for the proper formation of the jump. The remaining energy will be greater than that of Types I and II as the velocity over the weir is greater.

Type IV.—Pool Action.—Action of this type (Fig. 3) occurs if the weir of Fig. 1 is moved toward the dam. The basin is comparatively short and deep.

Instead of the smooth action of Type I the water shoots in and out of the basin and is thrown into the air. The pool surface is generally smooth except for a decided bump over the weir, and a slight roller is formed. The remaining energy is again greater than that of Types I and II as the water is thrown high into the air.

Type V.—Spray Action.—This type of action is illustrated in Fig. 4 and occurs if the basin is too shallow to hold the water. The length is of little importance as the sheet moves swiftly across the floor until it encounters the weir. It is then sprayed into the air. In this type, too, the remaining energy at the weir is greater than that of Types I and II.

These five types of stilling basin seem to classify the forms of action satisfactorily. The dividing lines between the types naturally are not clear cut and distinct, because one type merges into another. In Types I and II as contrasted to Types III, IV, and V, the basin is of such proportions that sufficient energy is dissipated to allow the water to flow smoothly over the weir. The energy remaining is definitely calculable, and its effects may easily be determined. Types I and II, therefore, are considered the more satisfactory kinds of action. It is the purpose of this study to define the conditions under which each of the types of action will occur and then to present a method of design by which a stilling basin may be proportioned to obtain any desired type of action.

While the ultimate test of the effectiveness of any stilling basin is its ability to prevent dangerous scouring, a clear knowledge of the factors that affect the operation of the basin and the relationships existing between these factors for satisfactory or unsatisfactory action will be helpful.

FIG. 4.—TEST 453, TYPE V: STILLING BASIN, SPRAY ACTION.

TEST METHODS

The experiments were performed in a timber flume, 2 ft. wide and approximately 20 ft. long, with a glass-sided flume a little more than 6 ft. long at the lower end. (See Fig. 5.) Water was supplied by a pump with a capacity of 1 000 gal. per min., from a measuring basin under the floor of the laboratory to a tank (constant level) on the hill back of the laboratory. From this tank, the water flowed through a pipe line into the flume, over the model dam, and back into the measuring basin. Cross-connections were provided so that direct circulation could be used on the larger quantities. A Venturi meter was inserted in the pipe line and a valve was placed at the inlet to the flume. Four sets of baffles, set about 13 ft. up stream from the model dam, successfully smoothed the flow. A hook-gauge well was located 6 ft. up stream from the model.

The dam was built of wood with a cross-section as shown for Series *B* (Fig. 5). Its surface was smoothed and painted carefully with several coats of shellac. Alterations were made at the toe to obtain the cross-sections of Series *A* and *C* (Fig. 5). The weirs that formed the stilling basins were constructed of 2-in. material and were fastened to the floor of the glass flume. Their rating curves, determined experimentally, are shown in Fig. 6, in which, D_w denotes depth of water at the weir (height of weir plus head on the weir) required for smooth flow over the weir, and D_j is the depth of water required in the basin for the formation of a hydraulic jump.

FIG. 5.—DETAILS OF TIMBER FLUME AND MODELS.

In running the tests a weir of given height was fastened to the floor at a given distance from the dam. The water was then circulated through the system and the quantity over the dam was adjusted by the intake valve. After conditions had become steady, readings were taken of the quantity and depth, and notes were made of the stilling-basin action. During the first runs, the Venturi meter was used to determine the quantity of water flowing over the dam and simultaneous readings were taken of the hook-gauge. As soon as a satisfactory rating curve had been built up for the dam, the Venturi meter readings were discontinued, except as an occasional check.

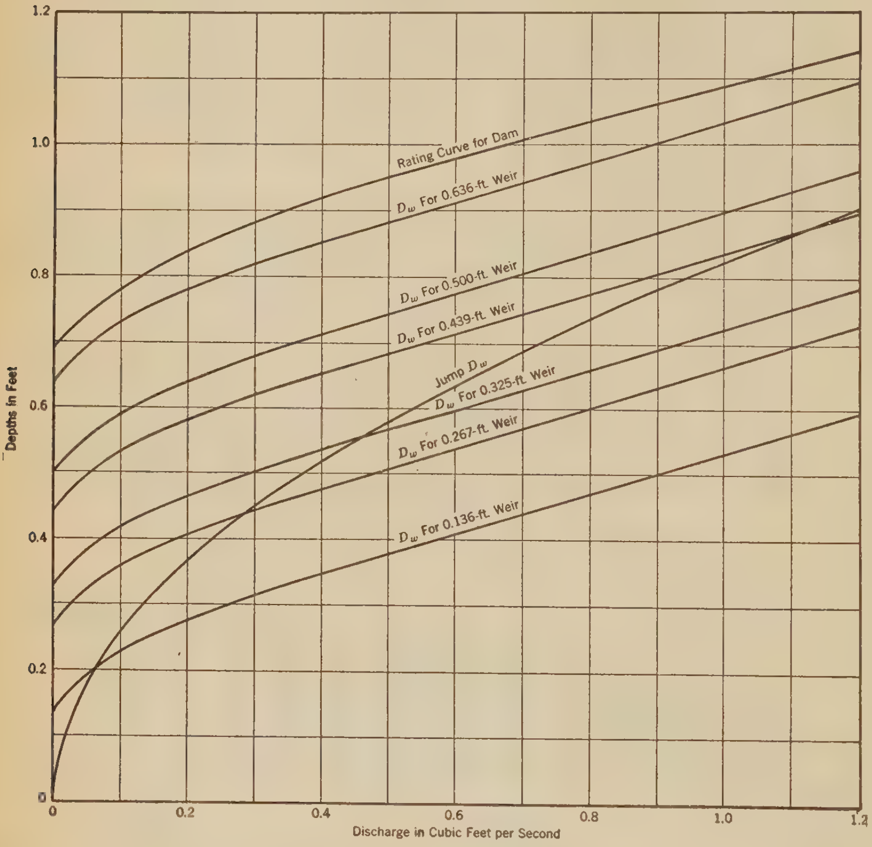

FIG. 6.—RATING CURVES FOR DAM AND WEIRS.

All readings of depth and length were taken by direct observation of the water surface through the glass by a grid painted on the glass with horizontal and vertical lines spaced 0.1 ft. apart. Notes were recorded regarding the action of the stilling basin and from these data the action was classified into the five types previously described. On many tests, sketches were made of the action in the stilling basin, and, in some cases, photographs were taken.

The tests were divided into three series (*A, B,* and *C*) for three variations in the form at the toe of the dam. (See Fig. 5.) The method of testing was the same in each series. The data include the height of weir, test number, length, quantity, and type of action from the observed notes. The computed values of D_j, D_w, and the ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, are also shown, in which, L is the length of the basin. Table 1 illustrates the manner in which data for 350 tests were assembled and arranged for use in this study.

Rating curves were built up experimentally for weirs of different heights and from these the values of D_w were obtained. The depth of water required for the formation of a hydraulic jump for various discharges was computed (assuming no friction on the down-stream face of the dam) by the hydraulic-jump formula:

$$D_j = -\frac{D_1}{2} \pm \sqrt{\frac{2\,V_1^2\,D_1}{g} + \frac{D_1^2}{4}} \quad \dots\dots\dots\dots\dots\dots(1)$$

in which, D_1 and V_1 represent the theoretical depth and velocities at the toe of the dam, and g is the acceleration due to gravity. The values of D_j were then plotted in Fig. 6. The ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, were computed from the complete record of which Table 1 is a condensed example.

METHOD OF COMPARING TESTS

A number of methods of comparing the test data have been tried in an attempt to find one that would segregate the tests according to the observed types of action. The most satisfactory method proved to be the plotting of two ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, for each test. These ratios have a definite meaning which must be kept clearly in mind if the test results are to be interpreted properly.

The first ratio, $\frac{D_w}{D_j}$, is the depth required for smooth flow over the weir with a given discharge, divided by the depth required in the basin for the formation of a hydraulic jump with the same discharge. Let W be the height of the weir and h_w, the required head on the weir; then, D_w will be equal to $W + h_w$. Since D_j is determined from the hydraulic-jump formulas, it depends on the velocity at the toe of the dam and on the quantity of water flowing over the dam. The velocity is dependent upon the height, slope, friction, etc., of the dam. A ratio of unity means that the basin is proportioned so that the depth required for the given discharge over the weir is just that required for the formation of a hydraulic jump under the existing conditions. Ratios greater or less than unity mean that the basin is deeper or shallower than required for the formation of a jump.

140......	1.2	0.785	1.15	0.74	0.65	0.88	1.85	IV

The other ratio, $\frac{L}{D_w}$, is the length of the basin divided by the depth required at the weir and is an index of the remainder of the proportions of the basin. When $\frac{D_w}{D_j}$ is unity, the second ratio, $\frac{L}{D_w}$, becomes $\frac{L}{D_j}$, or the length divided by the depth required for the formation of the jump.

These ratios thus tie the action of the stilling basin closely to the fundamental factors of the hydraulic jump.

Test Results, Series *A*

Each test of Series *A* has been plotted in Fig. 7, according to its value of the ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, with the resulting type of action designated by the mark used in plotting the data. It is easy to draw dividing lines between the five types of action. This is proof that there are definite types of stilling-basin action and that these may be segregated according to the ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$.

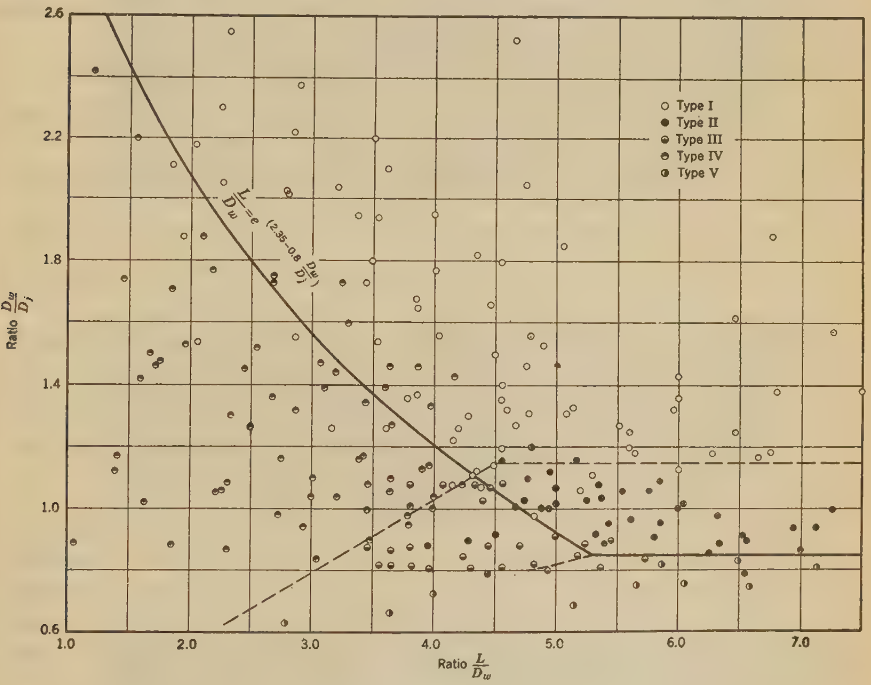

Fig. 7.—Ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, Series *A*.

The solid curve in Fig. 7 marks the division between Types I and II which are above the line, and Types III, IV, and V, which are below it. Types I and II may be considered satisfactory in that stilling-basin dimensions have such proportions that the excess energy is absorbed completely from the water, allowing it to flow smoothly over the weir. In Types III, IV, and V, these requirements are not fulfilled, and the basin does not function satisfactorily.

An analysis of Fig. 7 shows that Type I may be expected to occur whenever the dimensions of the bay are such that the point plots above the curve and above the line, $\frac{D_w}{D_j} = 1.15$. The action classified as Type II occurs when the ratio, $\frac{D_w}{D_j}$, is between 0.85 and 1.15, or substantially equal to unity, and the ratio, $\frac{L}{D_w}$, exceeds about 4.5. In other words, the depth of the pool must be that required for the formation of a hydraulic jump and the length of the pool must be not less than about 4½ times the depth of the jump. These values check with the commonly accepted requirements of a hydraulic jump, thus confirming the idea that Type II is essentially a hydraulic jump.

Types I and II, which are considered satisfactory, occur whenever the ratios plot above the curve until it reaches a value of $\frac{L}{D_w} = 5.31$. After that, the curve is a straight line, $\frac{D_w}{D_j} = 0.85$. Whenever the ratios plot below this curve, action will be unsatisfactory and will be of the classes characterized as Types III, IV, or V. Type III occurs when the ratio, $\frac{D_w}{D_j}$, is between 0.85 and 1.15, and $\frac{L}{D_w}$ is slightly less than that required for a jump. Type IV action occurs whenever the length or the depth is below that required for Type I. Type V action occurs whenever the ratio, $\frac{D_w}{D_j}$, is less than about 0.85 and occurs regardless of the length of the pool.

Figs. 8, 9, and 10 have been prepared to show the effect upon the basin action of changes in the fundamental variables. It is to be noted particularly that the tests are grouped in sets and that Figs. 9(*a*), 9(*b*), and 9(*c*) are parts of two sets; thus, Set 1 comprises Figs. 8(*a*), 9(*c*) and 8(*b*); Set 2 is represented by Fig. 9(*b*), as an example; Set 3 is represented by Figs. 8(*c*) and 8(*d*); Set 4 is represented by Figs 9(*a*) and 10(*b*); Set 5 includes Figs. 9(*b*), 9(*c*), and 9(*d*); Set 6 comprises Figs. 10(*c*) and 10(*a*); Set 7 is represented by Figs. 9(*c*), 10(*a*), and 10(*b*); and Set 8 is shown in Figs. 10(*c*), 9(*d*), and 10(*d*). In each set only one variable has been changed and the others have been held constant. In Fig. 11, the ratios applying to the illustrated tests are plotted and are studied in relation to the dividing line between satisfactory and unsatisfactory action in Series *A*. A study of the views and curves clearly defines the effect of changes in length, depth, height of weir, and discharge.

FIG. 10.—EFFECT OF DECREASING HEIGHT OF WEIR, W.

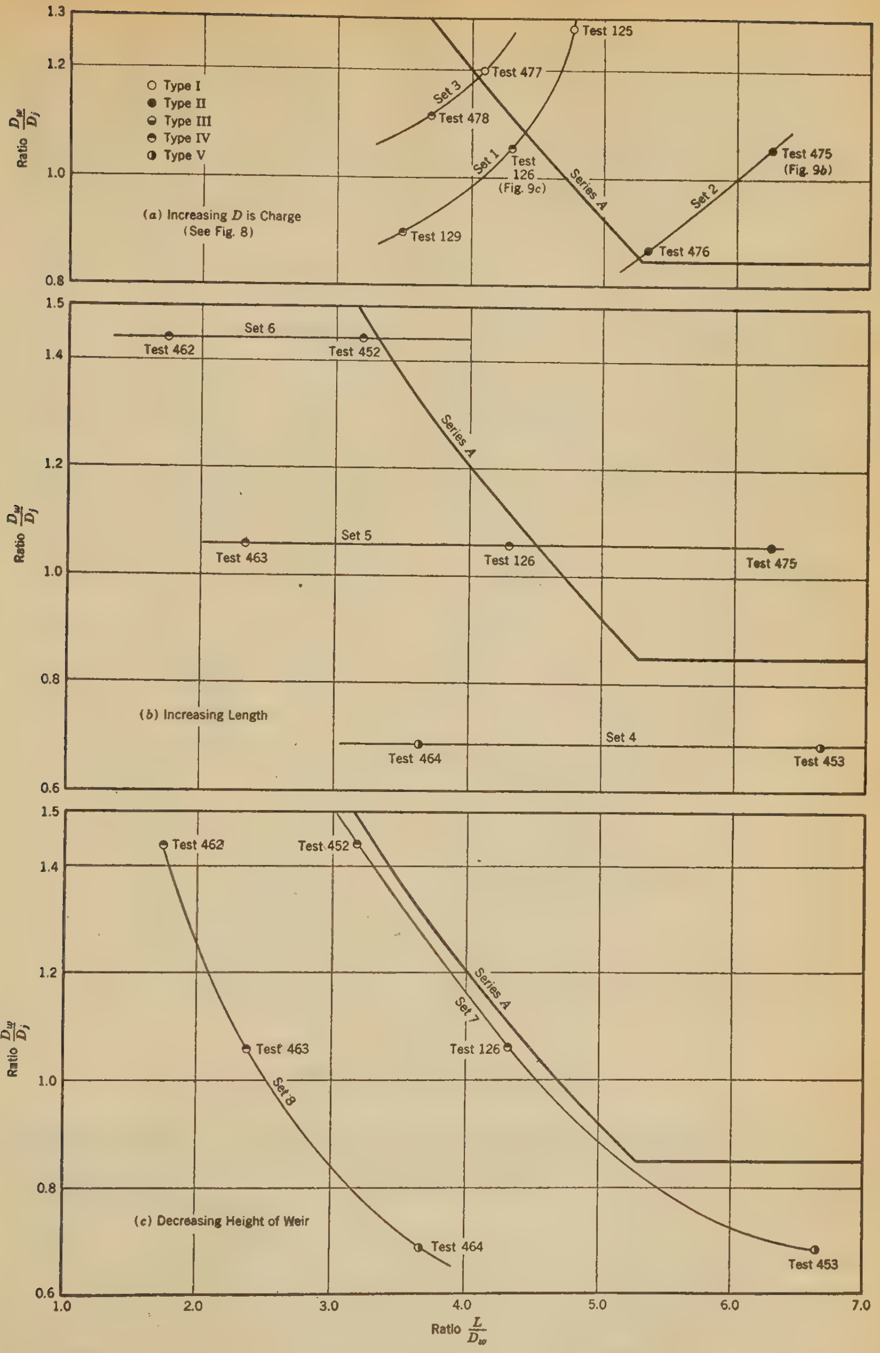

FIG. 11.—RELATION BETWEEN RATIOS, $\frac{L}{Dw}$ AND $\frac{Dw}{Dj}$, SERIES A; (a) INCREASING DISCHARGE (SEE FIG. 8); (b) INCREASING LENGTH (SEE FIG. 9); AND (c) DECREASING HEIGHT OF WEIR (SEE FIG. 10).

TEST RESULTS, SERIES *B*

The tests of Series *B* were performed similar to those of Series *A*, except that the 6-in. radius at the toe of the dam was removed, leaving the dam in its original cross-section as shown on Fig. 5. No attempt was made to run as complete a set of tests with Series *B*, as it was desired merely to check the curve of Series *A*. Nevertheless, the tests were run covering the entire range used in Series *A*. Fig. 12 shows the tests of Series *B* plotted with ratios of $\frac{D_w}{D_j}$ against ratios of $\frac{L}{D_w}$. The solid curve seems to satisfy the data down to the point where $\frac{D_w}{D_j} = 0.8$. This curve is identical with the curve of Series *A*, except that a constant, 1.10, has been subtracted from the exponential function indicating that the basin of Series *B* is considerably more effective than that of Series *A*.

It was considered unnecessary to draw the dividing line between Types I and II and between Types III, IV, and V. It seems logical that the basin of Series *B* should be more effective that that of Series *A*, although the magnitude of the difference was rather surprising. With the 6-in. radius of Series *A*, the sheet of incoming water is turned to a horizontal direction with little disturbance, while with the vertical cut-off it impinges with considerable force upon the floor of the bay. A roller or eddy is also created between the vertical face of the dam and the sheet of incoming water.

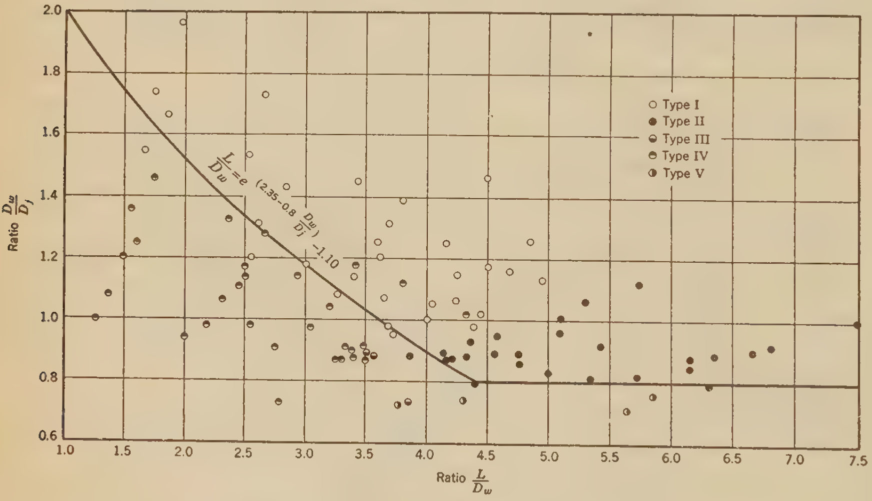

FIG. 12.—RATIOS, $\frac{D_w}{D_j}$ AND $\frac{L}{D_w}$, SERIES *B*.

One other reason for the difference in the effectiveness of the two bays is the method of measuring the length of the bay. In both cases, the measurement is made from the up-stream face of the weir to the intersection of the down-stream slope of the dam with the floor of the flume. This means that with the vertical cut-off, the basin is actually about 0.3 ft. longer than the basin of Series *A* for a given position of the weir. This variation in length accounts for part of the difference in operation, but is not sufficient to account for it entirely. It is obvious that the bay of Series *B* with the vertical cut-off is more effective than that of Series *A*. No attempt has been made to show curves and views of Series *B* such as those shown of Series *A* in Figs. 8, 9, and 10, because they would be similar.

TEST RESULTS, SERIES *C*

The tests of Series *C* and the curve for Series *B* are plotted in Fig. 13 by ratios of $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$. The basin of Series *C* was similar to that of Series *B*, except that a triangular strip of moulding was placed on the vertical face, as shown in Fig 5, to approximate a design of the tumble bay proposed[3] by A. F. Meyer, M. Am. Soc. C. E. Only a few tests were run in Series *C*; but there is no indication that the curve for this series should be other than that of Series *B*, indicating that the Meyer bay has its effectiveness in the vertical cut-off rather than in the overhanging lip.

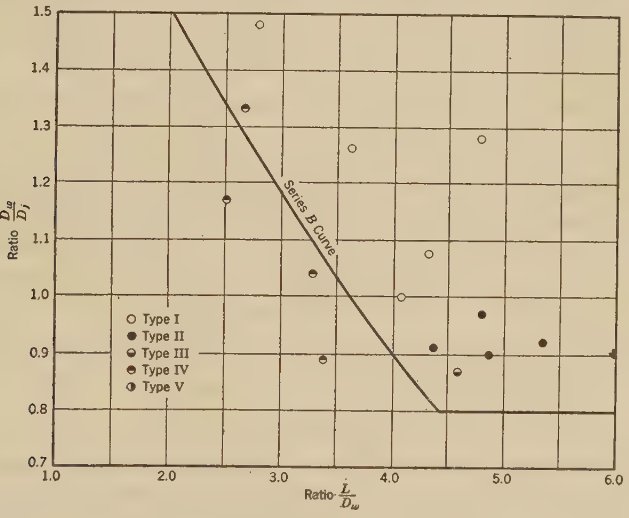

FIG. 13.—RATIOS, $\frac{D_w}{D_j}$ AND $\frac{L}{D_w}$, SERIES *C*.

EFFECT OF SHAPE OF DAM

The difference between the curves of Series *A* and Series *B* indicates that the shape of the dam has considerable effect upon the action of the stilling basin. The three forms tested in Series *A*, *B*, and *C* (Fig. 5) are entirely too few to set up any definite relationship as to the effect of the shape of the dam. The model dam was built with a down-stream slope of 60° with the horizontal, and there was no opportunity to try other slopes. Differences in action would be expected with differences in slope of the down-stream face of the dam as well as in differences in construction at the toe of the dam. It is to be expected that the steeper the slope, the more effective will be the action of the basin, at least for action of Type I. In the case of a hydraulic-jump action of Type II, it is possible that a flatter slope would allow the jump to form more easily, thus decreasing the length of basin needed for the complete formation of the jump. Certainly, it may be said that the vertical cut-off principle, as illustrated in Series *B*, is more effective than the bucket of Series *A*. There is need of further research to determine the effect of the shape of the dam on stilling-basin action.

---

[3] "High Velocity Discharge of Overfall Dams and Forms of Spillway Profile," *Engineering News-Record*, April 9, 1925.

EFFECT OF SHAPE OF WEIR

All the tests were run with weirs of similar cross-section, that is, one with a vertical face, horizontal top, and a square corner on the up-stream face. There seems to be no reason to believe, however, that change in the shape of the weir would alter the basic relationship of type of action and the ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$. A change in the shape of the weir would change only the value of D_w. It may be assumed that the weirs used in the test had a coefficient of about 3.3, and that a weir with properly designed crest might have a coefficient of 3.7. This would result in a slight decrease of the value of h_w for a given quantity, but as D_w is $W + h_w$ for a given quantity, it would change D_w even less. The result would be an effective height of weir less than that of the test. As the difference in heights of weir produced no differences in the fundamental relations, the differences in shape of weir could not affect the results.

EFFECT OF SUBMERGENCE OF WEIR

A few experiments were made in an attempt to establish quantitatively the effect of submerging the weir. The number of tests was too few to arrive at any definite conclusions. However, it may be said that the immediate effect is to require a greater head on the weir to discharge a given quantity of water. As a result the value of D_w is increased and the ratio, $\frac{D_w}{D_j}$, will also increase with a constant quantity. The other ratio, $\frac{L}{D_w}$, will be decreased slightly but, as D_j is normally much smaller than L, the change in the ratio, $\frac{D_w}{D_j}$, will be of greater magnitude than that of the ratio, $\frac{L}{D_w}$. As a result the depth of the basin is sufficient to handle a greater quantity; hence, the capacity to dissipate energy is increased by submergence of the weir.

INTERPRETATION OF TEST RESULTS

The conclusions presented herein may be summarized, as follows:

(1) The action of the stilling basin is closely connected to the phenomenon of the hydraulic jump.

(2) The ratios, $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, serve satisfactorily to classify the action of a stilling basin into the five types described.

(3) For satisfactory action of a stilling basin, the ratio, $\frac{D_w}{D_j}$, must be greater than 0.85.

(4) For any value of $\frac{D_w}{D_j}$ greater than 0.85, there is a corresponding minimum value of the ratio, $\frac{L}{D_w}$, that determines the minimum proportions of a stilling basin for satisfactory action. As the ratio, $\frac{D_w}{D_j}$, increases the ratio, $\frac{L}{D_w}$, decreases.

(5) Increasing the length of a basin to obtain a ratio of $\frac{L}{D_w}$ greater than this minimum value, does not improve the action. The ratio, $\frac{L}{D_w}$, need never exceed 4.0 or 5.0, depending upon the ratio of $\frac{D_w}{D_j}$, and upon the design of the dam.

DESIGN OF STILLING BASINS

The design of a stilling basin for any given dam is naturally dependent upon local conditions. A number of basins with varied proportions of depth and length $\left(\text{that is, varying ratios of } \frac{D_w}{D_j} \text{ and } \frac{L}{D_w}\right)$ may be designed to meet a particular height of dam and discharge, as has been discussed herein. The selection of the proportions for a given dam will depend principally upon foundation conditions. Whether or not the basin should be relatively deep or shallow is principally an economic question, the solution of which will depend on the elevation at which satisfactory foundations may be obtained for the dam and the stilling basin. The problem of whether or not the weir is to be submerged will also be principally one of economics; so, also, will be the question of the type of construction to be used at the toe of the dam. Although the vertical cut-off requires a shorter basin, it is accompanied by an additional quantity of concrete in the dam itself. Hence, no general design may be presented to meet all conditions, and satisfactory action will be obtained if the recommended proportions of the basin are used; but the actual design will differ with local conditions.

For design purposes, the solid curves of Figs. 7 and 12 may be plotted on one sheet as a guide to show the minimum ratios of $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, for action with dams constructed as in Series *A* and *B*. The required values of D_j for various heights of dam and various depths of discharge over the dam may be taken from a set of curves computed by Equation (1). The writer suggests plotting height of dam against D_j as ordinates for various values of head on the crest. The height of dam is taken as the vertical distance from the floor of the basin to the crest of the dam. The proportions for basins in which the action will be satisfactory may be readily determined from such curves.

Need of Further Research

In conclusion, the writer wishes to urge further research on this problem. The effect of submergence upon the capacity of a given basin to dissipate energy should be studied further. In studying the effects of the shape of a dam, various slopes as well as various constructions at the toe should be investigated. A series of experiments to determine the resulting scour below the weir for various basins, proportioned from the data included in this paper, would be desirable. Experimentation to determine what part of the basin requires a concrete floor to prevent erosion within the basin should also be made. Such research will lead to additional data of value in establishing a rational method of designing protective devices for overflow dams.

DISCUSSION

E. W. Lane,[4] M. Am. Soc. C. E. (by letter).—The best form of protection against scour at the toe of an overflow dam depends on the relative elevation, over the full range of discharge anticipated, of the natural tail-water level below the dam and the water-surface elevation required to form the hydraulic jump on a horizontal apron at the stream-bed level. When the tail-water level is below that required to form the jump, the best form of protection often is to increase the depth of the tail-water, either by increasing the water depth by excavation, or by raising the tail-water level by a secondary dam. For the latter case, if the flow over the secondary weir is not effected by the tail-water level down stream, the data contained in Mr. Stanley's paper are of great value to the designing engineer, and the profession is indebted to him for making it available. Since the tail-water level can rise above the crest of the secondary dam—if ogee in shape, two-thirds as high as the head-water—without materially influencing the discharge, the data will apply directly to a large range of conditions.

An extensive series of model tests similar to those of Mr. Stanley was made in 1930-31 for the design of the spillway of the Cle Elum Dam of the U. S. Bureau of Reclamation. This spillway was designed for a maximum discharge of 40 000 sec-ft and a water surface drop of 110 ft. It was of the trough type, controlled at the upper end by gates. The width at the upper end was 200 ft. At the middle this was narrowed to 100 ft and expanded to 200 ft at the lower end, where it extended the stilling pool. The trough was 900 ft long, and its shape as well as that of the stilling pool was developed by model tests. As there was no rock within reasonable depth, the entire structure was founded on gravel. The height of the tail-water was insufficient to form the hydraulic jump on an apron at stream-bed level, but instead of building a secondary weir to secure the depth necessary for jump formation it was obtained by depressing the pool bottom 11 ft below the river-channel bottom.

An extensive series of tests was undertaken to determine the best form of stilling basin. A model of the spillway on a 1:50 scale was set up in the hydraulic laboratory of the Colorado Agricultural College, at Fort Collins, Colo. The effectiveness of the various forms of stilling pool was determined by the scouring effects in a bin in which sand was formed to simulate the river bed down stream from the pool. Preliminary tests showed that duplicate runs would produce the same scour results, that the amount of compacting of the sand was of little importance, and that a run of 1 hr was sufficient to secure practically the same result as a flood of great duration in the spillway.

The first design of the stilling pool provided a horizontal floor, 102 ft long, down stream from which was a section 44 ft long sloping upward

---

[4] Research Engr., U. S. Bureau of Reclamation, Denver, Colo.

11 ft to river-bottom level, followed by a 10-ft level floor. The tests showed considerable scour at the end of this floor, which could not be corrected by sills. A steeper upward sloping section produced even less desirable results. Much better success was obtained by making the floor level throughout, 11 ft below river-bed level, and permitting the rise from the pool floor to the river-bed level to be formed in the river bed down stream from the pool.

Although fairly satisfactory results were secured with a simple pool with a level floor, the scour was less if some form of sill was placed at the down-stream end of the floor. These sills were in no sense secondary weirs, as were those used in the author's experiments, since they did not control, or even materially influence, the tail-water level. The height of most of them was only about 30% of the water depth. Their function was to form an eddy behind them, at the down-stream edge of the floor in which the current in contact with the river bed moved up stream and dragged bed material up toward the end of the floor, rather than scouring it away.

A number of types of sill were used. The one on which most of the tests were made was the dentated type introduced by Dr. Theodor Rehbock.[5] Another had an ordinary ogee dam section, and a third was trapezoidal in section with a 45° slope on its up-stream side and with a vertical down-stream face. All these sills were located at the down-stream edge of the apron. Most of them had a height of 10 ft. Tests were made, however, which showed that greater scour occurred with smaller heights and less with greater heights. The 10-ft height was used because the volumes of higher weirs, particularly in the case of the dentated sill, became excessive for great heights. All these forms gave good results, those obtained with the dentated sill being slightly better than the others, and the dentated form was adopted for the structure.

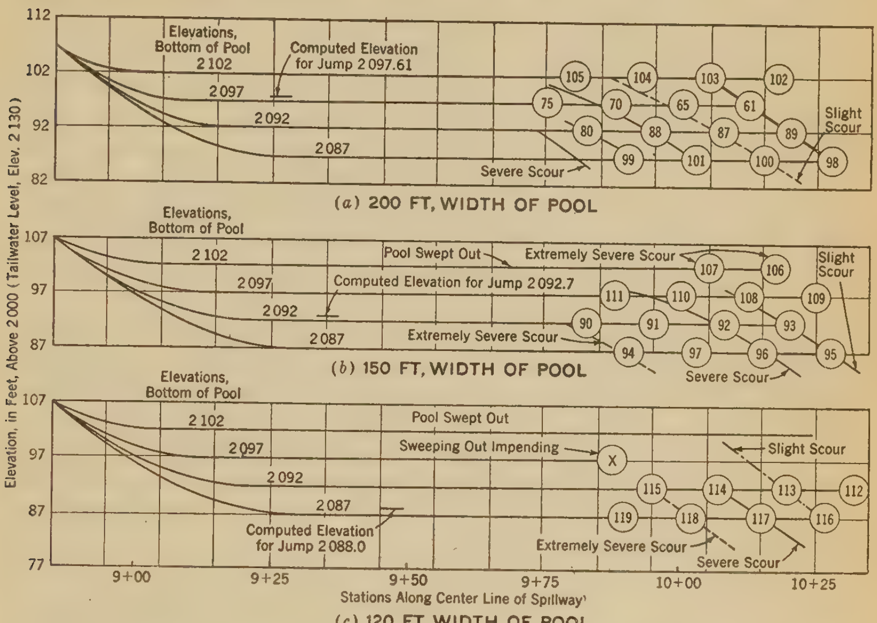
Tests were made to determine the best slope for the floor entering the stilling pool. Slopes of 1 on 1.5, 1 on 2, 1 on 3, and 1 on 4, were tested. In most cases the scour increased as the slope became steeper; it is believed that this was due to the fact that the hydraulic jump forms more perfectly with the flatter slopes. With the dentated sill the scour was practically the same at all slopes and since other considerations favored steeper slopes, the 1 on 1.5 slope was adopted for the structure. Tests also showed that with a curved surface between the sloping incoming floor and the level pool bottom less scour was produced than when there was no such transition. This also is believed to be due to the fact that the curved surface tended toward the formation of a more perfect jump.

In order to secure the greatest economy in the construction of the pool, extensive experiments were performed to determine the best combination of width, depth, and length. Experiments were made with pool widths corresponding to 200, 150, and 120 ft. For each width three or four pool depths were used and with each depth, several lengths were tested. In all, thirty-eight conditions were investigated. The 10-ft dentated sill was used in all tests and the discharge and tail-water level was that corresponding to the maximum expected flood. The scour of the bed down stream from the floor was slight in all cases, but the action on the banks differed considerably. The results were unusually consistent, which gave considerable confidence in them.

---

[5] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 527.

A comparison of the tests is given on Fig. 14, in which the various widths, depths, and bottom elevations are shown, and lines representing equally severe scour on the channel sides are drawn. The tests numbers are in circles, and the location of the circles indicates the end of the pool floor in that test. The results indicate that the severity of scour increased as the pool length was decreased, but that the scour was not decreased by deepening the pool. The former result might be reasonably expected, but a decrease of scour with increased depth seemed probable, due to the greater volume of water in the pool with the greater depth and, therefore, a greater dissipation of the energy.



(*a*) 200 FT, WIDTH OF POOL

(*b*) 150 FT, WIDTH OF POOL

(*c*) 120 FT, WIDTH OF POOL

FIG. 14.—COMPARATIVE SCOUR WITH POOLS OF VARIOUS LENGTHS, DEPTHS, AND WIDTHS

The results showed that for the same pool length, the severity of the scour was nearly independent of the depth as long as the jump remained in the stilling basin. This action is believed to be due to the more efficient formation of the jump with the smaller tail-water depth. With high tail-water levels the jump forms on the sloping floor leading into the pool. In such cases, the incoming water tends to dive under the water in the pool without causing a well-formed jump. As the tail-water level is lowered, the jump forms farther down the slope where the bottom is more nearly level; the tendency to dive under is less, and a more perfect jump is formed. This tendency to form a more perfect jump at smaller depths offsets the advantage in the greater depths, of the greater mass of water in which to dissipate the energy, with the result that the efficiency of the basin is independent of the depth, as long as the jump remains in the pool.

If the floor was raised too high, the depth was insufficient to cause the hydraulic jump in the stilling basin and the pool was swept out, as in Runs Nos. 106 and 107 (Fig. 14(*b*)). Such conditions produced severe scour on the sides of the earth channel down stream from the pool, but no severe scour on the stream bed. For each width, the elevation of the pool floor required to provide the theoretical height for the jump is indicated. It was possible to have considerably less depth than the jump theory indicated, without causing the pool to sweep out. Part of this difference may be due to the fact that the sills obstructed the flow somewhat and caused higher tail-water depths in the pool than in the stream below, where the tail-water elevation was observed. All the difference can scarcely be accounted for in this way.

The author obtained similar results, as is shown by the existence of many Type II conditions with values of $\frac{D_w}{D_j}$ less than unity. In the design of the stilling basin for the Cle Elum Dam, the full theoretical depth was provided, as a factor of safety, to take care of bed retrogression or other contingencies. The length of the pool adopted was that giving a "a slight scour" condition as indicated by the author's Fig. 1, and rip-rap was provided to protect against the scour. Economic rather than hydraulic considerations led to the selection of the 200-ft width for the prototype. These three requirements were met by a pool 100 ft long, 200 ft wide, and a floor 33 ft below the tail-water level for 40 000 sec-ft discharge.

When the dimensions of pools producing slight scour are expressed in terms of $\frac{D_w}{D_j}$ and $\frac{L}{D_w}$, and plotted as in the author's Figs. 7, 12, and 13, they indicate lines roughly parallel to the inclined portion of the solid line on Fig. 7, which divides the satisfactory from the unsatisfactory cases, but they give lower values of $\frac{L}{D_w}$. For the experiments with the 200-ft bottom, the corresponding values of $\frac{L}{D_w}$ are only two-thirds as great as the author's Series *A*. For the experiments with the 150-ft and 120-ft widths they are even less, being only 58% for the latter width. There are several factors which may account for this difference. One is that the incoming slope for the Cle Elum experiments was 1 on $1\frac{1}{2}$ as compared with 1 on $\frac{1}{2}$ (approximately) in the author's experiments. The flatter slope would probably give a more efficient hydraulic jump. Furthermore, on the flatter slope, the jump would begin farther up stream from the point where the pool was assumed to begin, which was at the intersection of the incoming slope with the pool floor, and, therefore, for a given nominal pool length, the effective length would be greater for the flatter slope. A third factor is that in the Cle Elum type the pool may continue in effect beyond the end of the floor, as the sill does not obstruct the flow, but only protects the bed from scour.

In order to make the results of the Cle Elum tests as readily applicable as possible to other conditions, Fig. 15 has been prepared. It is based on the assumption that the distribution of discharge in the experiments was uniform across the entire pool, and on the theory of model similitude. The foregoing assumption is believed to be substantially true. Suppose, for example, it is desired to design a spillway for a discharge of 25 000 sec-ft and a fall of 80 ft (plus friction loss) from reservoir level to tail-water level. The velocity head of the water entering the stilling basin, at the elevation of the tail-water, would then be 80 ft. Entering Fig. 15 with this value gives a model ratio of 43. This means that if the model experimented on had been considered to be a 1:43 model (instead of a 1:50 model as was required, in order that it meet the conditions for the Cle Elum Dam), the proportions would be correct for a velocity head of 80 ft.

Since, by the model theory, the form tested would represent a 1:43 scale as accurately as the 1:50 scale, the model would represent reliably the desired conditions as well as those at Cle Elum Dam. With a model ratio of 43, the lines representing discharge per foot of pool width show 135, 170, and 220 sec-ft per ft of width as determined from the experiments with model pool widths of 4.0, 3.0, and 2.4 ft, respectively. For a discharge of 25 000 sec-ft, a pool 114 ft wide would be required if the discharge was 220 sec-ft per ft of width as determined from the 2.4-ft model pool. The line representing depth of pool tail-water level based on the 2.4-ft pool width shows for a 1:43 model, a depth of pool below tail-water level of 36 ft, and the similar line for length of pool required, for a 1:43 model gives 99 ft. Since the sill height of the model was 0.2 ft, that required would be $0.2 \times 43 = 8.6$ ft high. Thus, Fig. 15 shows that a pool, 114 ft wide, 99 ft long, and 36 ft deep, with a sill 8.6 ft high, would meet the required conditions.

Other pool dimensions equally suitable, could be obtained from the lines representing the results determined from the 3.0 and 4.0-ft model pools. Of these three sets of dimensions, the most advantageous from the standpoint of cost or other considerations, may be chosen. Care should be exercised, however, to use throughout the dimensions determined from the lines based on the same model pool width, and not to use, for example, the depth obtained from the 4.0-ft model pool and the length as indicated by the 3.0-ft pool. It is recognized that the dimensions indicated by Fig. 15 may not be very practical in certain cases. This simply means that the Cle Elum model tests are not applicable to those cases, and data must be sought elsewhere for their design.

In applying this diagram the following conditions to which it is applicable should be kept in mind: The flow must be equally distributed across the stilling pool and in the direction of its axis. The tail-water rating curve at the site must be such that ample pool depth is available at all discharges to cause the jump to form in the basin. The top of the sill must be sufficiently below the channel bottom so that a drop of the water level will not result at any discharge from the obstruction caused by the sill. There will be considerable wave wash on the sides down stream from the pool, and rip-

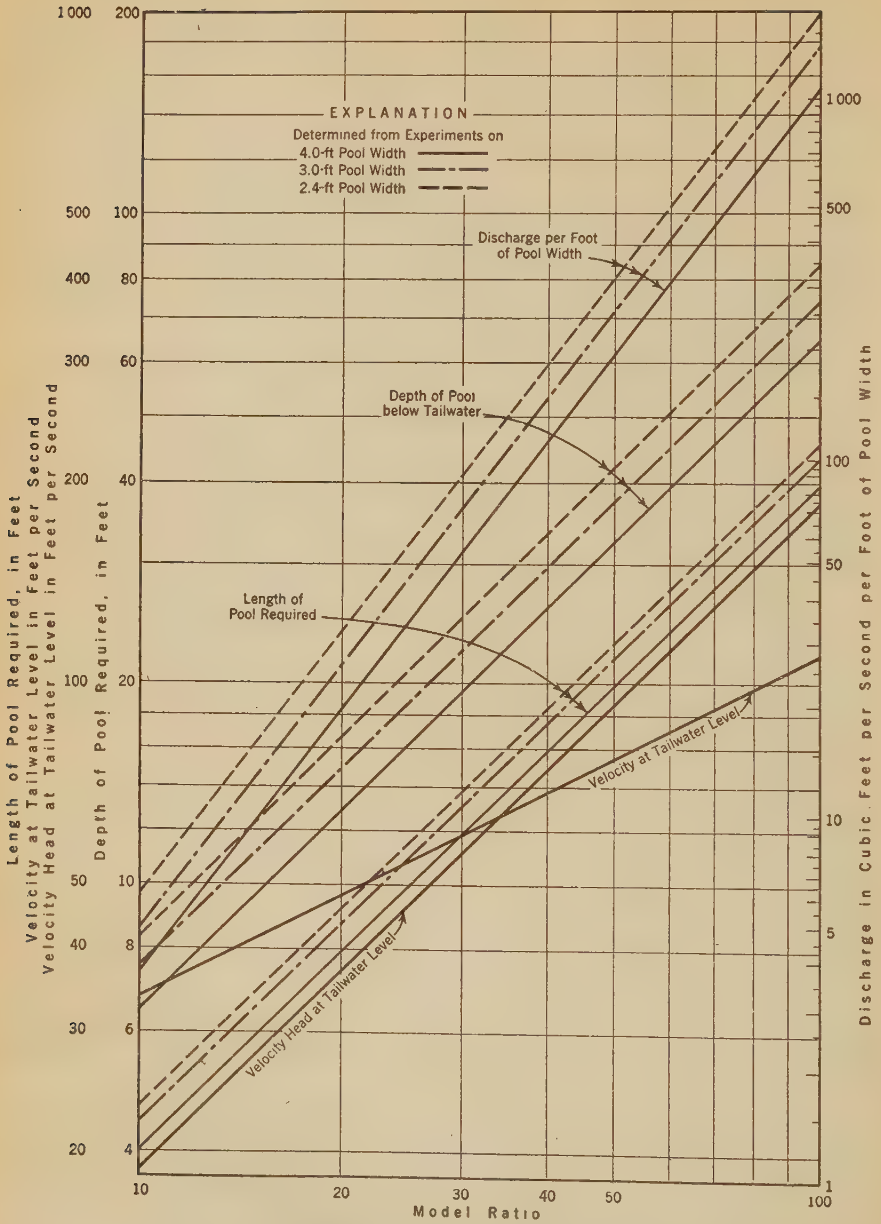


FIG. 15.—DIMENSIONS REQUIRED FOR STILLING POOLS AS SHOWN BY RESULTS OF MODEL TESTS

rap protection will be required, especially if the pool is intended to be used over long periods at flows approaching its capacity.

Although the experiments were performed with a dentated sill it is believed that the ogee or beveled sill types could be used with slightly less desirable results. The experiments were performed with a slope of 1 on 1.5 entering the pool and a transition curve at the bottom of the slope. It is believed that flatter slopes with the transition curve would produce equally as good results, but that the effects of steeper slopes might be less desirable. The writer agrees heartily with Mr. Stanley that "the day is not far distant when experiments with models will be a necessary part of the design of every overflow dam." The data given herein, therefore, should not be considered as removing the necessity of model tests, but only as the basis for preliminary designs, to aid in narrowing the field to be covered by the model studies, and for the design of unimportant structures of insufficient magnitude to bear the expense of model tests.

C. C. INGLIS,[6] ESQ. (by letter).—For the very narrow limits of the experiments—namely, two-dimensional parallel flow, horizontal bed, and free flow-away down stream—stilling basins of Types I and II give highly satisfactory results; but this is only a special case of a very great problem. More generally, dissipation of energy is a three-dimensional problem, and eddies with vertical or complex axes cause much damage. Where energy has to be dissipated and eddies have to be prevented in canals, a combination of a "baffle" and a "deflector" has given satisfactory results in Sind.[7]

The baffle is made equal in height to the free-flow depth and is constructed at a distance from the toe equal to $5\frac{1}{4}$ times the free-flow depths. The baffle is fixed at such a level that, with the natural down-stream water level, the wave will form at the toe of the fall—under which conditions the standing wave dissipates the maximum amount of energy. The deflector is fixed at the end of the pavement, and is equal in height to one-twelfth the maximum depth of water.

The falls and regulators of the Sukkur Barrage Canal in Sind, have been designed as proportional meters. This involves fluming down to about one-half the natural bed width. The convergences have been standardized at 1 in 5 and the divergences at 1 in 10, although sharper divergences have been used in several cases. Under such conditions the corkscrew eddies, which form near the banks below falls, are accentuated and—especially where the divergences are sharper than 1 in 10—cause scour at the sides down stream.

Such scour, if not severe, can be prevented by '"tarungars"—wire crates containing stones—which should be laid sloping downward at a slope of 1 on 5. A neater solution is to use deflector-grids; but perhaps the best solution is to lower the pavement, joining it to the side slopes by elliptical curves with the deflector continued up the side slopes.

---

[7] "The Dissipation of Energy Below Falls," by C. C. Inglis and D. V. Joglekar, *Technical Paper No. 44*, Public Works Dept., Bombay, India.

Where the divergences were sharper than 1 in 10, it was found necessary to fan out the flow to prevent return flow. This was effected by building vanes in continuation of the piers, the vanes being splayed as found best in model experiments.

The results obtained with baffles, deflectors, and vanes have proved highly satisfactory, whereas several other methods—including the one described by the author—when tested, using large models, gave much inferior results.

F. KNAPP,[8] ESQ. (by letter).—The author deserves credit for the experiments made to rationalize the design of stilling basins at the toe of an overflow dam. Especially valuable are Figs. 7, 12, and 13, which show the relationships between the fundamental and controlling factors. Mr. Stanley classifies five distinct types of stilling-basin action, Types I and II (the most efficient) being identified as roller and jump action, respectively. The writer does not feel satisfied with the distinction between these types. From the description given under the heading "The Stilling Basin," Type I can also be considered as jump action with the nappe submerged by tail-water. Type II represents free nappe with repelled jump. According to B. A. Bakhmeteff,[9] M. Am. Soc. C. E., the ratio,

$$\frac{\text{Difference of elevation, between head and tail-water}}{\text{Height of dam}}$$

defines the two types of jumps. Type II requires a ratio > 0.75 and Type I, a ratio < 0.75 approximately, the correct value depending on the over-flow conditions of the dam. Experimental observations by Bazin confirm Professor Bakhmeteff's deductions.

Under the heading "The Results, Series *A*", Mr. Stanley states that the action classified as Type II occurs when the ratio, $\frac{D_w}{D_j}$, is between 0.85 and 1.15, or substantially equal to unity, and the ratio, $\frac{L}{D_w}$, exceeds about 4.5. In other words, the depth of the pool must be that required for the formation of a hydraulic jump and the length of the pool must not be less than about 4.5 times the depth of the jump. There are cases, however, that require a ratio, $\frac{L}{D_j}$, considerably greater than 4.5. Fig. 7 shows this ratio varying from 4.6 to 7.2 for Type II action and a ratio, $\frac{D_w}{D_j}$, equal to unity. With the length of the pool determined, either theoretically or empirically, the problem of designing a stilling pool for Type II action, would be solved. This length may be determined by the following considerations.

The loss of energy in a hydraulic jump is always smaller than the Borda-Carnot loss, $\frac{(V_1 - V_j)^2}{2g}$. A certain distance is required before shooting water in the jump can be slowed down to normal, flowing water. Consequently, with the velocities changing gradually, the loss of head produced by the jump must be smaller than $\frac{(V_1 - V_j)^2}{2g}$. In other words, there must be a relation between the length of the jump, L, and the loss of head in the hydraulic jump, namely $\left(d_1 + \frac{V^2_1}{2g}\right) - \left(d_j + \frac{V^2_j}{2g}\right)$. Based on published experiments[10], the writer has deduced the following empirical formula (in metric units) for the length of the jump:

---

[8] Designing Engr., The Sao Paulo Tramway, Light & Power Co., Ltd., Sao Paulo, Brazil.

[9] "Hydraulics of Open Channels," *Engineering Societies Monographs*, New York and London, 1932.

$$L = \left(62.6 \frac{D_1}{H_1} + 11.3\right) \left[\frac{(V_1 - V_j)^2}{2g} - (H_1 - H_j)\right] \dots\dots\dots (2)$$

in which, $H = d + \frac{V^2}{2g}$.

Unfortunately, it is not possible to present a comparison of this formula with the results obtained by the author. The writer is unable to check the depth, D_1, of the jump from the values of discharge and the depth, D_j, given in Table 1. The writer hopes Mr. Stanley will clarify this point in his closing discussion.

C. MAXWELL STANLEY,[11] JUN. AM. SOC. C. E. (by letter).—Discussions of this subject served to emphasize certain parts of the paper and to raise certain questions regarding the applicability of the methods of design suggested therein. The writer wishes to express his appreciation of these contributions.

The discussion, by Mr. Lane, of the test data from the Cle Elum Dam of the U. S. Bureau of Reclamation is particularly interesting. The results of these experiments in stilling-basin design check closely the results submitted in the paper. Mr. Lane points out that in the model study of the stilling basin for the Cle Elum Dam, the results parallel the inclined position of the solid line on Fig. 7, which divides the satisfactory from the unsatisfactory cases, but that lower values of the ratio, $\frac{L}{D_w}$, were obtained. He suggests three factors which may account for this difference: (1) The flatter incoming slope which would allow a more efficient hydraulic jump; (2) the fact that the jump would begin up stream from the point at which the pool was assumed to begin; and (3) the effect of the Cle Elum type of pool may continue beyond the end of the floor as the sill does not obstruct the flow but only protects the bed of the river from the scour.

There is little question but that the flatter incoming slope will allow the formation of a more efficient jump. This fact was encountered in the writer's experiments and in the analysis of the effect of the shape of the dam he indicated the possibility that a flatter slope would allow the jump to form more easily, thus decreasing the length of basin needed for the complete formation of the jump. The fact that the jump will form on a slope also produces the effect of requiring a shorter stilling basin. The third condition (the possibility of action continuing below the end of the pool), is related to the effect of submergence upon the weir. As mentioned in the paper, experiments were run with the weir submerged and while these experiments were not sufficiently extensive to permit any complete analysis, it was very apparent that with a depth of water below the weir sufficient to submerge it, the capacity of a given stilling basin to dissipate energy was increased.

---

[10] "Untersuchungen über den Wechselsprung," von Safranez, *Der Bauingenieur*, 1929, No. 38, p. 676.

[11] Engr. (Young & Stanley, Inc.), Muscatine, Iowa.

The writer would like to suggest a fourth reason why the results of the Cle Elum tests indicated satisfactory operation at lengths somewhat less than those found in his own experiments. In the latter experiments satisfactory operation was separated from unsataisfactory operation merely by observation of the flow over the weir. If this flow was smooth, indicating that turbulence had been removed, the action was classified as satisfactory. It was hoped to supplement this with further experiments using an erodible bed below the weir. It is the writer's opinion that it is unnecessary to remove all the turbulence from the water prior to passing over the weir in order to avoid erosion below it. This should be particularly true with submerged conditions similar to those used on the Cle Elum test.

The effect of the weir is twofold: First, it creates a certain pool depth, and, second, it acts as a sill to create an eddy, or roller, about a horizontal axis immediately down stream from the weir. The direction of this roller is such that the water in contact with the bed of the river flows up stream toward the sill and thus prevents erosion. This phenomenon has been observed in numerous model studies, and advantage has been taken of it in the design of many protective devices below spillways.

Mr. Inglis questions the applicability of the data to any except a few special cases. He brings out the fact that dissipation of energy is a three-dimensional problem. This is true, but if the spillway, or stilling basin, is of any considerable length, the eddies or currents at the side will affect only a limited length of the basin, and the major part of the design must be based on the two-dimensional condition similar to that studied. Proper care must be taken of the action of the side currents and eddies. Such actions will be special cases for every project as they are concerned with local topography to a considerable extent.

Mr. Knapp does not feel satisfied with the distinction between Types I and II and suggests that Type I can be considered as jump action with the nappe submerged by tail-water, while Type II represents free nappe with repelled jump. The difference in action between Types I and II, as shown in Figs. 1 and 2, is very distinct, and there was nothing in the appearance of the action to suggest that Type I is a form of jump action. It is merely a stream of water shooting into a pool, flowing along the bottom of the pool, and, at the same time, creating a roller or eddy about a horizontal axis.

One point, which has been stressed by Mr. Lane and also by the writer, is worthy of further mention. This is the fact that the design of a stilling basin for any particular project is not only a matter of hydraulics, but also one of economics. For any condition there will be a number of combinations of length, depth, and submergence which will dissipate satisfactorily the energy from the falling water, and the choice of a particular design will depend on the relative costs. Hence, it is an economic problem.

In conclusion, the writer wishes to emphasize again the need of additional research to determine more clearly a rational method of design of stilling basins. The need of research on the effect of different slopes of the dam and upon the submergence of the basin is particularly apparent from the tests on the Cle Elum Dam.

If this paper serves to stimulate further research in this field, it will indeed have served its purpose.

A PROBLEM OF SOIL IN TRANSPORTATION IN THE COLORADO RIVER

By S. L. Rothery,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. E. Grunsky, Ivan E. Houk, H. M. Rouse, William T. Collings, Jr., R. F. Walter, Harry F. Blaney, Calvin V. Davis and Dirk A. Dedel, Thaddeus Merriman, J. C. Allison, and S. L. Rothery.

Synopsis

This paper is concerned principally with the problem of excluding soil, transported by the Colorado River, from the Canal System of Imperial Valley, in California. Its purpose is: (*a*) To feature the relative importance of the bed load of the Colorado River and to provide some conception of the extent of the unknown volumes of soil transported; (*b*) to present known and anticipated future river-flow conditions pertinent to soil conveyance; and (*c*) to propose fundamental requirements for a diversion structure that will exclude all the bed load and a part of the suspended load, thus permitting minimum sizes for—or, perhaps, eliminating as unnecessary—the enormous settling basins which are expected to desilt the large diverted flow, and also permitting lessened sluicing operations for the disposal of the sludge.

The publication of specific research and a pooling of available knowledge before a design for such an important diversion is finally adopted, may suggest a solution for the automatic exclusion of much of the soil load. Each 1 000 000 cu. yd. of soil that is prevented from crossing the sill of the headgate, can represent an annual saving of tens of thousands of dollars if relief must be obtained by dredging. With 10 000 000 cu. yd. of soil automatically excluded, such savings are probably in the hundreds of thousands of dollars, depending on the remedial measures that have to be taken when such large

[1] South Pasadena, Calif.

volumes of transported soil are continually arriving on the down-stream side of the diversion gates. In part, these savings are represented in the form of lessened maintenance operations throughout a vast canal system, in channels and sinks for waste-water disposal, as well as in the ditches of the individual ranches.

INTRODUCTION

As a background for a thorough understanding of the problem reference is here made to a paper on the subject by the late C. E. Grunsky, Past-President, Am. Soc. C. E., published in 1929.[2] As they apply to the intended purpose of this paper, the following items of information from that paper are summarized:

(1) The water supports and carries its suspended load throughout the entire length of the Imperial Canal. Sometimes there is less, and sometimes a little more, sediment in suspension at the head of the canal than at points 20 to 40 miles below but, generally, when the water is extremely muddy at the head it stays muddy throughout the entire length of the canal.[3]

(2) A phenomenon that illustrates the occasional conditions favoring the temporary conversion of the bed load of a river into a suspended load is the formation of a standing wave. This is noted in streams of moderate depth, flowing in beds with fine sand bottoms. It is a common phenomenon on the Lower Colorado River.[3]

(3) In 1918, the head-works of the canal were modified, suction dredges were installed, and, in a period of 30 months, nearly 15 000 000 cu. yd. of material was excavated. While it is not quite clear what effect this had on the lower reaches of the Imperial Canal, it is certain that if it had been allowed to remain in the canal, it would have traveled down stream to the annoyance of the Canal Management and the farmer.[4]

(4) The dredging did not relieve the canal of its bed load entirely. The dredged sumps in the head of the canal did not trap all the silt that came over the flash-boards of the Rockwood Gate. Even 500 000 cu. yd. per month does not represent the entire load of fine sand carried as a bed load by the canal. How much more was being transported is not known, and no entirely satisfactory basis for estimating it has been found.[4]

(5) Assuming that there must have been some débris and other material held in suspension temporarily during ordinary flow conditions, the bed load of the Colorado River (with its annual discharge of about 15 000 000 acre-ft. of water at Yuma, Ariz.) should be about six or seven times as great as that of the canal, or 25 000 to 30 000 acre-ft. per year.[4]

(6) Observations at Yuma in 1914 indicated that when the Colorado River was heavily charged with silt, the settling was nearly always slower than when the silt load was light. The Imperial Canal does not hold quite

[2] "Silt Transportation by Sacramento and Colorado Rivers and by the Imperial Canal," by the late C. E. Grunsky, Past-President, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1104.

[3] *Loc. cit.*, p. 1113.

[4] *Loc. cit.*, p. 1117.

as much silt in suspension as the river. The water in the canal is less turbulent and the heavier grains of silt drop down and become part of the bed load.[5]

(7) Turbidity in the river varies with depth. The increase of the suspended load downward from the surface bears no fixed relation to the loads at the surface or at mid-depth. The increase with depth is nearly constant in the sense of being independent of the total suspended load, the increase of percentage being 0.11 from the surface to the bottom. In other words, if the percentage by weight at the surface is represented by P, that at the bottom is $P + 0.10$.[6]

(8) The Colorado River is not as muddy at low stages as at moderately high stages, as, for example, a discharge of 15 000 to 50 000 sec-ft. The river is muddiest when it is discharging 15 000 to 30 000 cu. ft. per sec. Turbidity is highest in the early spring and in the fall.[7]

(9) Perhaps there are other causes affecting the degree of muddiness. For example, the silt in the lower river shows many signs of being dispersed, that is, the colloidal particles seem to be carrying negative charges. Possibly, the source of the water and its chemical composition affect the degree of dispersion, or of flocculency, as the case may be, and, therefore, cause a greater or smaller volume of silt in suspension. When clays are dispersed, each flocculated particle splits into many subdivisions, sometimes so small as to be colloidal.[8]

(10) Table 11[9] of Mr. Grunsky's paper shows that in periods, such as October to December, 1925, and January, February, June, and July, 1926, the suspended load increases with the distance below the Grand Canyon; in other periods, it remains fairly constant. In September, 1926, there was even a decrease of suspended load. These results seem to confirm the conclusion that, at times, the river picks up material from its bed and, at other times, it drops part of its suspended load.[10]

(11) The facts illustrated in Mr. Grunsky's Fig. 6[8] give no indication that can be used in estimating the bed load of the river, except possibly that a considerable portion of it originates below the Grand Canyon.[11]

The Bed Load

An average of 15 000 acre-ft. of silt, the equivalent of 24 200 000 cu. yd., has been diverted annually in suspension into the Canal System of Imperial Valley, California. In 1923, the peak quantity was 24 900 acre-ft., or 40 172 000 cu. yd. In addition to this quantity, large volumes of bed sand and coarse silt, estimated at more than 4 000 acre-ft.,[4] or 6 453 000 cu. yd., have been transported as the annual bed load along the Main Canal. The respective annual quantities transported on the Lower Colorado River are estimated to be: 94 000 to 111 000 acre-ft. of suspended soil, and 20 000 to 30 000 acre-ft. of bed load.[8] These estimates of the bed load are believed to be much too small.

At a great diversion works, 19 miles up stream from Yuma, provision is being made (1932) for a maximum inflow into a main canal of two to two and one-half times that of the present summer irrigation demand. Apparently, this should make possible, the doubling of each of the foregoing two soil quantities in the main canal if the intercepting influence of the huge reservoir formed by Hoover Dam could be excepted. A cost of $3 375 000 is listed tentatively for the construction of desilting works at the proposed site.

That the suspended load of the Colorado River, as now accepted,[12] is only a part of the total soil annually transported, is logically shown by the following reasoning applicable to the spring flood each year, as well as in a lesser degree when smaller floods or freshets occur. Consider, for example, the 300-mile stretch up stream from Yuma. The bed is filled with soil subsequent to several winter months of low-river stages; then 4 to 6 weeks of increasing flow to the flood peak in May or June completely removes a solidity of soil represented by the product of 300 miles, an average scoured depth of, say, 9 ft., and a river width of, say, 600 ft. Any material in this space is influenced by fluid velocities of 4 to 10 ft. per sec., and it is, therefore, impossible for deposition or up-stream travel of any sand or silt particles to refill the scoured prism before the discharge is in the decreasing stages. This product is equivalent to 316 800 000 cu. yd., or 196 400 acre-ft. of soil completely removed and transported hundreds of miles in a period of only a few weeks. On the other hand, the estimated soil volume carried in suspension averages about one-half this quantity for an entire year!

The scoured deepening is often more than 20 ft. At Yuma in 1907 and, again, in 1909, it was found that for an increase in the gauge height the bed was lowered approximately 30 ft.[13] River widths of flood stages are between 800 and 1 200 ft., and the time of travel from the Grand Canyon to Yuma is about 4 days in high-water stages. Therefore, the values given for the elongated prism of removed soil are conservative, and the entire length is at a scoured maximum simultaneously during the few days of peak flow.

The additional square feet of scoured area of cross-section probably cannot be expressed in a percentage of the water volume as solid material in motion, since the distance to deposition and the time unit of the flood duration do not seem to permit of a constancy of expression.

The velocity curve of a stream in a vertical plane is represented by the line, *A B*, in Fig. 1, the maximum velocity being in the upper half of the vertical depth, and the minimum at the stream bed. The fine silt particles that aggregate the "suspended" soil load, and that are responsible for the turbidity of the stream, are buoyed up and transported in the upper two-thirds to three-fourths of the stream depth with less effort on the part of the stream, than in the lower depth, while general uniformity of flow is maintained, as is the case of an irrigation canal whether it is 1 mile or 300 miles in length.

---

[12] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1142.

[13] *Loc cit.*, Vol. LXXVI (1913), p. 1214.

Particles too heavy to rise, or too granular to be retained in suspension (unless turbulence is produced by some cause to destroy uniformity of flow) are transported by rolling and saltation along the bed by the lesser velocities, which, however, are not much less than those above the center depth. The velocity of flow necessary to move fine sand is 0.70 ft. per sec., and, for coarse sand, 0.80 to 1.00 ft. per sec.[14] The mean velocities for flow conditions in the channels and canals of the Colorado Delta region are 3 to 6 ft. per sec.; so that with bed velocities known to be greater than 1.00 ft. per sec. in the more slowly moving canal water, when flood conditions exist in the river the travel of the bed load is both rapid and continuous.

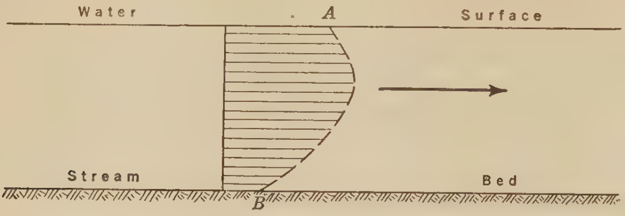

FIG. 1.

Some samples of the traveling bed load were collected at Grand Canyon from 1925 to 1928. When the sampling bottles were near the bottom with the mouths pointed up stream the silt content was 35% greater for a mean of sixteen samples, than when the samples were taken in the usual upright position. For six samples taken in a similar manner, but still nearer the bottom, the silt content was 40% greater.[15] Such increased percentages are properly part of the unknown bed load, if only for the reason that they have never been considered in estimating the suspended loads. This also shows that there is a traveling slurry of soil contiguous to the bed at normal river stages.

Consider such a fluid slurry in the lowest, say, 3-ft. depth of a large flood. Bed sand itself has no cohesive qualities, but it can have compactness when the interstices are filled with fine silt and when there is a weight due to depth of water above. The drag of increasingly scurrying velocities over it frets away the compacted particles, giving them initial movement and lessened weight due to becoming freely submerged. The loosened grains soon attain momentum, the velocity of which approximates that of the fluid influence surrounding them. This surely must be true for sand, since egg-sized pebbles are in motion with 3-ft. velocities, and boulders, 6 to 8 in. in diameter, are moved when velocities of 5 to 6 ft. per sec. are attained, and this latter rate is only the average mean velocity of Colorado floods.

If the sand load thus being shot along in the bottom 2 or 3 ft. of the flood, were represented only by a 3-in. average thickness of solidity for a 600-ft. width of river and averaging a velocity at the bottom of only 3 ft. per sec., the bed-load volume would be 17 cu. yd. per sec. at any given point, which is equivalent to 1 440 000 cu. yd. per day, or 60 000 000 cu. yd. in the 6 weeks of rising flood. Visualize this soil supply as coming from not any one given location, but from the continued welling up of the bed into fast fluid motion along hundreds of miles of this elongated soil prism. The 3-ft. velocity represents, say, 50 miles per day. Then, in a 300-mile length there would be a daily feeding of sand to the traveling load of 1 440 000 × 300 ÷ 50 = 8 640 000 cu. yd., which, if continuous for 6 weeks, or 42 days, becomes 360 000 000 cu. yd., or 223 000 acre-ft. of soil.

---

[14] "The Control of Water," by the late Philip A' Morley Parker, M. Am. Soc. C. E., p. 495.

[15] *Water Supply Paper 636-B*, U. S. Geological Survey, p. 26.

In the first flood stages, at 30 000 sec-ft., the traveling thickness of equivalent solidity may be, say, less than an inch, and at the flood peak it may be the equivalent of feet in thickness. Any value used must necessarily be an assumption. The writer is of the opinion that 3 in. as an average is too conservative, and that scour is a continuous process of excavation in a great depth of alluvium, until flood velocities have passed. If the discharge lessens temporarily, the water surface lowers; but scour and the rate at which sand travels are functions of the flood velocities which are maintained for some days after the flood peak has passed.

Assuming that the bed of the river is of alternate "deeps" and "shoals," so that it may be claimed that the effective length is reduced 50%, which would divide this great scoured volume in two, the result would still be greater than that of the estimated suspended load per year. This soil movement has been accomplished in six weeks from only a part of the channel.

A conspicuous example of the power of the river to excavate soil was described in a previous paper[16] wherein the writer stressed the transportation of such soil volumes in a unit length of 100 miles.

Anticipated River Flow Conditions Below Hoover Reservoir

The average annual run-off of the Colorado River is 15 000 000 acre-ft., with years of maximum precipitation yielding more than 20 000 000 acre-ft. The planned storage capacity of Hoover Reservoir is 25 000 000 acre-ft. Until large agricultural uses are developed up stream from the reservoir to consume the water, the river bed below the huge dam, in consecutive wet years, may have to take care of a flow nearly equal to the annual run-off. A regulated continuous flow of 21 000 sec-ft. throughout the year would provide this requirement; but, because of the necessity of conserving head at the dam for development of power, such steady flow will never occur, and the regulation of discharge will depend upon the down-stream uses, and upon the estimated up-stream flood inflows as to their effect on the surface elevation of the conserved water in the reservoir.

Down-stream uses are a minimum in the winter months. With a release of 15 000 sec-ft. for six months to provide these uses, including the quantity required for sluicing at the Imperial Diversion, 5 500 000 acre-ft. will have been discharged from storage by March, and this volume in a wet year may have been more than regained by inflow, so that the reservoir has been maintained as nearly full. The spring flood with 9 000 000 to 10 000 000 acre-ft.

---

[16] *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1412; also, *Engineering News-Record*, Vol. 95, (1925), p. 1068.

in 60 days (as in May and June, 1917, 1920, and 1921) would demand a release of 83 000 sec-ft. While this discharge will undoubtedly be reduced in the demand for regulated down-stream control, it is to be expected that the range of flow will be between 15 000 and 65 000 sec-ft. in the lower river after the Hoover Reservoir is filled.

The stream will be a different and chastened river, however, when the Hoover Dam is placed in operation. Although the river issues from the dam as clear water without its up-stream soil loads, 300 to 450 miles of soil-filled river bed are ahead; but its capacity for deep scour and for refilling with soil its channelized bed will have been greatly curtailed.

Since the profile gradients have resulted from the necessary velocities for silt-laden water in the alluvium, they will not be stable enough to produce and maintain the lesser velocities needed for the flow of clear water. The required gradients will be less steep and the stream, in striving to attain these new slopes, will continue to pick up soil loads, because the moderately high river stages are capable of transporting a maximum turbidity. The references (Items (8), (10), and (11)), to highest soil loads for discharges of 30 000 to 50 000 sec-ft., have their verification in studies by Raymond A. Hill, M. Am. Soc. C. E., from 3 000 samples taken between 1908 and 1916 at Yuma.[17] Mr. Hill calls attention to the fact that the characteristics of a desilted river cannot be based on data acquired when the river was heavily laden with silt and that no one can predict which rate of discharge from a flood-control reservoir will produce the most stable condition.

In commenting on the maximum silt content at discharges of 40 000 sec-ft., E. W. Lane, M. Am. Soc. C. E., states[18] that the redistribution of flow might even increase the silt removal to more than 80 000 acre-ft. per year.

Eventually (after several years), the required river gradients for clear water flow will become established through gradual recession working up stream from control locations in the bed, such as from the diversion dams of the Imperial Intake and of the Metropolitan Water District at Parker, Ariz.; and also from locations where rock or hard soil is close to the river bed. With varying discharges (the maximum being four to five times as great as the minimum), erosion, deposition, and meandering will still occur, although to a much lessened extent than with the extremes of flow of the unregulated river.

Tributary streams, notably the Williams River, will frequently contribute sudden freshets transporting coarse soils and sand, because the declivities of these side creeks and washes are relatively great. That of the lower end of the Williams River is more than twice the stream gradient of the Colorado for a distance of 10 miles from their confluence, and the high discharges are given as 7 000 to 9 000 sec-ft.[19] On August 5, 1931, a cloudburst on the Williams water-shed produced an increase of discharge from 7 000 to 45 000 sec-ft. over night.[20]

It is concluded, therefore, that both suspended and bed loads will be present in the curtailed river flows below the Hoover Reservoir. The suspended loads, however, are expected to decrease in extent to almost negligible quantities as the regimen of the stream becomes stabilized. Bed sands are expected to be present always, although in much lessened quantities when the channel has attained equilibrium.

The physical difference of the "suspended" silts and the "bed" silts has been described[21] concisely by Harry F. Blaney, Assoc. M. Am. Soc. C. E. He distinguishes between the mechanical analyses given in Table 19 and in Table 1 of Mr. Grunsky's paper, previously mentioned, to the effect that 73% to 95% of the "suspended" load was fine enough to pass a No. 200 sieve, but that only 1.7% to 34% of the canal "bed" deposits will pass such a sieve in which the separation of the meshes is 0.10 mm. From these respective tables it is noted that the coarsest "suspended" silt passes a No. 40 sieve (wherein the meshes are 0.48 mm.), and the coarsest canal "bed" silt or sand passes a No. 20 sieve (wherein the meshes are 0.95 mm.).

The great bulk of the suspended load of the present turbid flows, therefore, is seen to be of the finest soil particles, but the proportion of such particles in the alluvial soils of the river bed, resulting from recurring deposits of each receding flood, is undoubtedly only a small proportion of the bed soils.

Charles Terzaghi, M. Am. Soc. C. E., refers to a property of silts as being scale-like and fragile (see, also Item (9)), always sinking in stilled water with the flat side horizontal, whereas sand grains are of rounded and angular shapes. His analyses[22] afford an explanation of what is perhaps the fundamental characteristic difference between the "suspended" and the "bed" loads of the Lower Colorado. It is readily conceivable that lamina and disk shapes are more sensitive to support and carriage in fluid motion than granular ones.

The sieve analyses mentioned, also show similarity of sizes of particles in both Tables 1 and 19 of Mr. Grunsky's paper previously noted, although the relative percentages of fineness and coarseness differ. As a result of silt research on the Nile River in Egypt,[23] "coarse sand" was classified as that collected on a No. 100 sieve; "fine sand" as that passing the No. 100 sieve, but caught on No. 200 sieve; and silt and clay as that passing the No. 200 sieve. The coarse sand in suspension in the bottom 3 ft. where the Nile is 26 ft. deep, is given by Mr. A. B. Buckley as 16 times the quantity of such sand in suspension in the surface 3 ft.; that for the fine sand as 7 times the respective quantity; while that for the suspended matter—silt and clay—shows little difference, the bottom quantity being 1.2 times that in the surface water. This is in close agreement with Mr. Grunsky's findings for the suspended silt content of the Colorado River (see Item (7)), which content is, however, ten times that of the Nile.[24]

Therefore, the clear-water flow from the Hoover Reservoir, in the erosive process of flattening the stream gradients, will absorb readily into suspension the finer silts to aggregate the capacity soil load. The granular sands and coarser silts will contribute in a lesser degree to this load, until such suspensible matter, entrapped in the alluvial deposits, has been released and transported. In other words, the silts (and turbidity) will be eliminated from the bed soils of the channel first, leaving the sands to continue to move by rolling and saltation after the clearness of the stream has become established.

Furthermore, sand will always be present, more or less, because each year tributary streams and washes that have steep gradients, will add supplies of sand and coarse soils transported by the cloudbursts that are a climatic feature of the territory. The largest of these streams are the Williams River (which divides into the Big Sandy River and the Santa Maria River), Sacramento Wash, Tyso Wash, Bouse Wash, and Arroyo Seco. Again, with the decreased flows becoming more uniformly regulated in distant years, scoured channelized depths will cease to exist, and the curtailed stream will tend to assume a wide shallow cross-section that is virtually all bed (see Fig. 2, in which the greater distance (*a*) is the width of channel for a stream the bed of which is in sandy soil, and the distance (*b*) is that width for an equivalent stream volume flowing in soils that have cohesive qualities, as in silts and clays). Because in such a stream, the relative area of the bed to the wetted surface is great, giving a large transporting width, sand travel may be expected to be a continuous feature of the flow; therefore, any structural provision effecting its exclusion from the diverted irrigation water will be permanently beneficial.

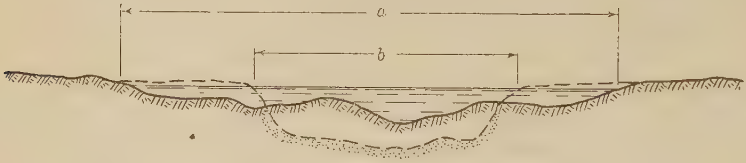

FIG. 2.

STRUCTURAL REQUIREMENTS FOR EXCLUSION OF THE BED LOAD

The quantity of sand and bed silt that has been passing through the headgate into the Main Canal is unmeasured. How much more than 500 000 cu. yd. per month (see Item (4)) is being transported is not known. Undoubtedly, the actual quantity has been more than twice the original estimate of 500 000 cu. yd. based on suction dredger yardage. The sumps to which Mr. Grunsky refers[25] for trapping the sand, are deep excavations in the bed of a canal more than twice too wide for the arc limits described by the suction head of the dredge swinging about a lowered spud. These sumps cannot be made too close to the canal banks. The traveling bed load fills the deep excavations rapidly as they are being made over, say, 50% of the bed width, while traveling past the dredger over the other 50 per cent. Shut-downs for

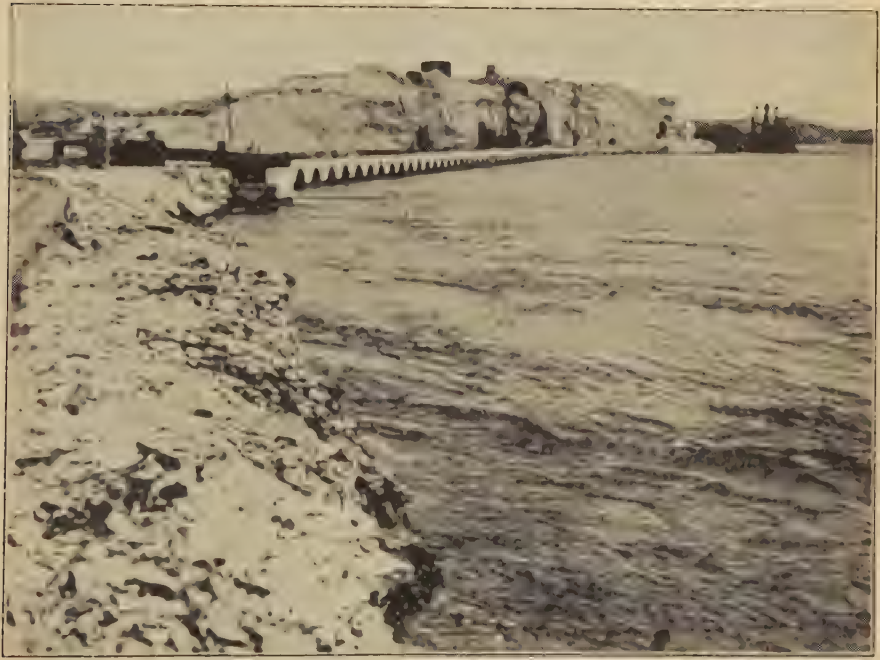

Fig. 4.—High Flood at Rockwood Intake.

repairs and while the dredger is advancing to new locations, represent time lost, giving the advantage to the bed load, the travel of which is ceaseless.

Fig. 3 shows extreme low-river conditions on the river side of the intake gate, the bed of the river being flush with the lowest sill of the structure. The "drag" on the bed in the direction of the intake is apparent. The structure is composed of seventy-six openings that invite the traveling bed load, except during flood conditions. Fig. 4 shows the flood conditions, during which the bed is probably at great depth below the sill, which is also raised several feet; but the sudden retardation of velocity of the canal inflow, contributes the bed load in the canal.

When extremes of discharge are removed, with scoured river conditions the head-gate sill should have a sluicing velocity below it, tending to sweep the traveling bed load past the structure without coming over the sill; but with a diversion taking the canal supply from a direction at right angles to the river, interference of uniform flow conditions (especially when the draw-off is relatively large) is produced in the division of the waters. The eddies and small whirlpool vortices thus formed, extend to some distance out stream from the structure, stirring the traveling bed load into suspension; whence, much of it is carried into the canal portion and over the head-gate sill, to be dropped again in the more slowly moving canal waters.

When the mixed-up turbulent flow of the river is suddenly quieted by the orderly diversion of, say, 10 000 cu. ft. of water per sec., there is a continued rain of soil to the bottom of the canal. When this is observed for 86 400 sec. each day, the structure responsible for it assumes a significance contrary to its intended purpose. Figuratively, the structure seems to reach down wilfully into the depths of the river to stir up and collect as much of the soil load as possible before it can escape, and place it in the canal on the down-stream side of the head-gate merely to cause annoyance and expense. Then the silt must be transferred back into the river again for final disposal, to prevent its becoming a menace throughout the Canal System.

The writer is of the opinion that a side offtake without under-sluices is an effective selector of bed silt. The drag on the river bed is toward the structure; raising the sill will obstruct the travel of the bed load only temporarily. The relatively small pocket in front of it is filled quickly to form a ramp sloping up to the sill elevation and permitting the travel to continue into the canal. Lowering the sill again causes the entire ramp to move in, offsetting the short respite gained while the pocket was being filled. Such a sill is, therefore, completely ineffective, apart from the turbulence (produced by the division of stream flow), which causes eddies and vortices to lift some of the approaching bed load into suspension to pass it through the diversion gates.

The greatest source of trouble and expense to canal maintenance and operations is removed if the bed load can be excluded entirely, and some added cost to effect this purpose is money well spent beforehand. When "sand is running,"[26] that phenomenon is visible in the disturbed hydraulic gradient and water-surface agitation for a length of several hundred feet in a main canal. The traveling bed sand accumulates in excessive volumes to constrict channelized flow in this canal, the uniform requirements of which are changed to whirlpools and turmoil. Whether or not there is surface evidence of the presence of blocks of sand, expense is involved for bank protection, dredging, or canal enlargement.

---

[26] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1113.

The traveling bed load should never pass through the diversion openings above the gate-sill. Furthermore, it is unnecessary to trap it in desilting basins or in dredged sumps. It must not be impeded or retarded in its travel of approach in the river before passing through the structure at an elevation lower than that of the gate-sill. A horizontal separation of the uniformly approaching flow to the structure is needed between the sill and a point some distance up stream, in order that the stream bed shall be kept beyond the influence of the contractural inflow through the diversion openings, thus preventing any disturbance on the approaching bed-load conditions. This can be effected by a light horizontal partition, supported on light walls, the upstream edge preferably having as much overhang as possible. No vortices or eddies can then penetrate to the traveling sand, which is disposed of through under-sluices without any slowing up or trapping by deposition to necessitate rehandling.

A diversion structure, placed across the river normal to the stream, provided with such a partition and under-sluices properly proportioned, will exclude, automatically, all the bed load and that part of the suspended load in the lower water that passes under the partition. Relative to the total suspended load this part is at least in the ratio of the depth below the partition to the full depth of the stream. The logical deduction for such a partition has been described[27] by Mr. F. Y. Elsden, including the final refinement to care for a varied range of water-surface elevations in the river. The refinement will not be necessary at the new Imperial Diversion, however, where a fairly constant river height will be maintained.

A necessary requirement is that the flow of approach be in a smooth uniform channel. When the diversion and under-sluices are passing the full river discharge for long periods, this is not difficult to attain, since the stream tends to stabilize its own approach channel; but when the diversion and open sluices are a part of the river discharge (the surplus passing through floodgates or over an adjacent weir), the stream division, or the accelerated velocities which are produced if the weir is too short, may require a longitudinal training wall extending up stream in the river for some distance, to assure that the approaching bed load of the diversion portion is not disturbed.

The correct weir length that will produce a minimum scouring turbulence with the high discharges, and a minimum of shoaling or deposition with subsequent return to low-water flow, is determinable. Should a long training wall be the solution for uniform approach to the diversion openings, care in determining its location is necessary to avoid shoaling in the approach channel, when the major portion of the river flow is passing through the floodgates or over the weir.

---

[27] *Water and Water Engineering*, October 20, 1923.

Figs. 5 and 6 show the diversion works as tentatively proposed, with the changes made to provide the features described herein as being necessary for the successful exclusion of the traveling bed load. The disposal of this soil through the diversion structure is preferably a continuous and unobstructed transportation to a free discharge, which is regulated in volume by the sluice-gates, into the river bed on the down-stream side of the structure. The diversion openings, canal flume, and the under-sluices call for a frontage to the river of 750 ft. and a length of about 450 ft., as shown.

FIG. 5.—TENTATIVE PLAN OF DIVERSION WORKS.

Figs. 7 and 8 show the works if desilting basins are to be used to obtain a partial deposition of the suspended load. The discharge from the under-sluices conveys the bed sand in a conduit that leads across under the lower side of the diversion gates, to empty through a gate-control well, into the river bed as before. Here, the works require a frontage of 1 200 to 1 250 ft. and a length of 1 550 ft. These illustrations are only diagrammatic.

The gates of the under-sluices may be closed to allow the bed load to accumulate. The partial deposition from the lower depth will then raise the bottom of the approach channel to the elevation of the diversion gate-sill, when the gates are re-opened to scour the bed down again. Thus, the under-sluices may be effective for either continuous or for intermittent sluicing operations. A flash-board or raised sill, 1 ft. to 2 ft. high, at the diversion gate would provide further leeway for raising the bed of the approach channel before re-opening the sluices.

A trash rack placed up stream at the under-sluices would prevent submerged driftwood from entering the structure. A footwalk supported on light piers rising from the horizontal partition at the under walls would furnish access for the removal of such driftwood; and flash-board grooves in these piers, with narrow openings through the horizontal partition to permit the lowering of the flash-boards, would be a means of closing the under-sluices in case of an emergency, or for inspection.

(*b*) ENLARGED PART PLAN

FIG. 6.—ENLARGED PLAN AND LONGITUDINAL SECTION OF DIVERSION WORKS.

Mr. A. B. Buckley states[28] that the direction in which the gates travel when opening, is an important feature for the exclusion of bed sand. Referring evidently to offtakes without under-sluices, he announced in 1922 that the difficulty due to silt accumulations at the heads of canals in India had been quite overcome. One canal was dredged every year for twenty years until it was discovered that if instead of the vents being opened from the bottom, they were opened from the top, the bed of the river was not scoured into the canal. This was said to be an almost infallible cure, but might not always be possible financially. Mr. Elsden has reported[29] that silt has been a source of serious trouble on many canals in India, but on none of them has it been necessary to resort to constant dredging.

DESIRABILITY OF INSTALLING DESILTING BASINS

The bed sand and heavier silt particles are quickly precipitated if the flow is stilled or greatly retarded; but this is not so for the suspended load, which requires a period of detention in quiescent water for several hours.

The rate of deposition of soil in suspension in still water from the Nile River in Egypt, was found[30] to be 2 min. through a depth of 25 cm. for the sands which comprised 10% of the sediment, and 3 days for the silts and clays to settle through 50 cm. The rate for the Colorado River was found[31] to be 2 hours through a depth of 1 m., to the extent that a definite mud deposit is formed, leaving the water apparently clear to the eye if not closely inspected.

If the flow in a long section of canal prism is stilled for sufficient time, the fine suspended silts settle slowly until they remain very lightly intersupported as a loose sludge on the bed. The slightest movement of the water, such as the resumption of flow, causes the settlement to be disturbed and the silts, which are readily susceptible to diffusion in fluid motion, are again in suspension unless precautions are adopted to minimize the disturbance of this undeposited sludge. One such precaution would be to have the stilling basin relatively wide at right angles to the canal flow, drawing off the quieted surface water from a point on the wide side. The inflow to the basin should be directed toward those wide parts most remote from the position of the outflow.

(c) CROSS SECTION

FIG. 8.—ENLARGED PLAN AND LONGITUDINAL SECTION OF DIVERSION WORKS WITH DESILTING BASINS.

Each 1 000 sec-ft. of flow stilled for 1 hour would require a basin capacity of 80 acre-ft., which is equivalent to a water area of 4 acres with a vertical depth of 20 ft. If the maximum diversion of 15 000 sec-ft. is to be detained for 1 hour, a capacity of 1 200 acre-ft. (or fifteen such basins), is needed, with as many more providing the draw-off to maintain constant diversion flow. Thus, thirty such basins with a water area of 120 acres (requiring a total area of, say, 200 acres of ground) are necessary to obtain only 1 hour's detention of the flow, not even considering desludging operations and time required to fill the basins. A further increase of probably 50% would be required for the desludging operations. Each additional hour of detention would be a direct multiplication of the extent given.

The tentative layout in Fig. 7 shows six basins on an area of about 37 acres which is equivalent to twelve city blocks, each 300 ft. square, inclusive of streets 60 ft. wide. It could be effective only for the removal of the bed sand and coarse silts, by effecting a retardation only, of the velocity of flow. Even for this limited area a cost item of construction for desilting works is stated to be $3 375 000.

Are these great costly basins necessary? The bed load can be eliminated without the intervention of desilting basins, but the suspended loads cannot be so eliminated and then decreased only in a slight degree, since the necessary desilting area and desludging operations assume too great a magnitude to permit of sufficient detention of large diversion flows.

It has been reasoned in this paper that the suspended silts diminish in quantity as the changing river gradients gradually become stabilized to the new conditions below the Hoover Reservoir, and that after some years the clear-water flow will transport only bed sand.

New irrigation laterals and ditches, required on 300 000 additional acres to be irrigated in Imperial and Riverside Counties, California, will be constructed in sandy soils which, unlike the present irrigated area of Imperial Valley, are not composed of Colorado River alluvium. It may be a double mistake to deprive these new watercourses in porous soils, of the beneficial effect of silty flow, and to deprive the ranchers who are reclaiming windswept sandy acreage from the silt that would be added to his fields if the desilting basins were effective in its removal.

Water containing silt would be an assistance proffered by Nature to these new developments, and advantage of it should be taken before the laterals begin to carry the subsequent clear-river water. Silty flow is advantageous because: (1) It contributes to the prevention of seepage, the fine silt particles gradually filling the interstices in the loose sandy canal sides and bottom, thus sealing these seepage passages; (2) it helps to maintain depth by giving stability to the side slopes of canals in sandy soils; (3) it will kill all aquatic growth by excluding light; and (4) it will give added surface soil which is also claimed to have a fertilizing value, to the rancher who has sandy land.

However, this added soil is of negative value to the long-suffering ranchers who farm the heavy alluvium of the present irrigated area; and impatience to obtain clear water is a factor that must be considered, if such water can be obtained even at high cost. A sudden conversion to clear-water flow will undoubtedly result in additional costs for canal maintenance, and this is an adverse factor to the change.

The arguments in this paper can be summarized as follows:

(*a*) The traveling bed load can be removed without desilting basins.

(*b*) The traveling suspended load cannot be greatly reduced with desilting basins, because the period of detention must necessarily be too long for precipitation of the fine silts.

(*c*) The suspended load will be a diminishing quantity with the stabilizing of new river gradients, and will not exist after a few years.

(*d*) Silty canal flow is desirable to new acreage during the years after the porous soils comprising the mesa lands are first reclaimed.

(*e*) Impatience and sentiment from the large agricultural communities of Imperial Valley may demand that all possible efforts be made to obtain clear-water flow in the canals, when the new diversion is effective.

Items (*a*), (*b*), (*c*), and (*d*) do not favor justification for 40 to 100 acres of huge desilting basins with large desludging structures, and subsequent daily sluicing operations. Item (*e*) may overrule the other four, in which case competent investigation, with some research, may be well worth while to determine factors governing the rapid desilting of fine silts, in order to obtain a minimum magnitude of works and of subsequent operations.

References have been made in Item (9) and in other places as to the colloidal phenomena in Colorado River water.[32] Particles of colloidal dimensions cannot be precipitated without the presence of an electrolyte, which may have to be added to cause flocculation. However, it is not believed that the term, "desilting," is intended to apply to this requirement for the purposes of clarifying irrigation water.

CONCLUSION

The assumptions used in this paper to estimate volumes are necessary to visualize the greatness of the transported loads. They are very conservative; even greater values for the basic dimensions would be nearer to actual conditions. If cross-sections could be taken simultaneously 10 miles apart over a 100-mile stretch of the Lower Colorado River, weekly between March 15 and the day of the flood peak in late May or June, actual data would be available for interesting comparisons.

If a suggestion has been made pointing to a less cumbersome solution to the problem of soil exclusion at the new diversion than that of constructing the necessarily enormous desilting basins, the effort taken to prepare the paper will have given some satisfaction. A desilting structure on the lines suggested, will be as efficient as the basins; it will be more economical in first cost of construction and in operation; and it will be far less unwieldly because flow velocities are not interrupted. With such a structure available when the river flow has become clear, there will be no reason for the basins, but without it they will always be necessary.

The conclusions are briefly stated as follows:

(1) The volumes of soil transported by the Colorado River have been greatly misconceived, chiefly due to the generally accepted viewpoint that

---

[32] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1130.

the bed load of flood discharges is stirred up to constitute the suspended load. This is disproved by the greatness of the cubic contents moved by recurring deep scouring during short periods, at least once each year and almost without exception.

(2) The bed load is the principal source of trouble; it contains a much smaller percentage of the fine silts than the suspended load. The difference in the shapes of soil particles offers an explanation for the chief characteristics that distinguish between the bed load and the suspended load, respectively. Granular shapes, when raised into suspension by vertical eddies, tend to sink when they are released from the vertical influence. Therefore, in transportation, they are most dense close to, and along, the bed. On the other hand, the laminar shapes, which in quiescent water sink with their flat sides approximately horizontal, are susceptible to diffusion and retention with the least movement of the fluid in which they are supported, so that flow conditions find the suspended silts uniformly distributed throughout the stream section, for the entire length of the river or canal.

(3) The exclusion of the bed load from any large diversion flow is more important and can be accomplished more easily than that of the suspended load.

(4) Desilting basins of minimum size will trap the bed load by retarding the velocity of flow, so that it can be disposed by subsequent sluicing operations. However, they will not desilt the suspended loads unless it is possible to stop the flow completely for a number of hours. This requirement calls for desilting areas of such magnitude as to be cumbersome and economically non-feasible.

(5) Silty canal flow, without a traveling bed load, has several advantages to the reclamation of 300 000 acres of undeveloped lands on porous soils.

(6) Turbid conditions will gradually lessen and practically cease to exist after an unknown period of several years, when the changed river gradients have become established below the Hoover Reservoir, due to the clear-water discharge from it.

(7) Bed sand will always be in transportation, even when clear-water flow has been established, the silts being first washed from the alluvial channel bed, by meandering of the stream and recession of gradients. With flood velocities modified, the transportation of sand will be slower but continuous, due to additional supplies being contributed yearly from tributary streams and sand washes. This is also due to the fact that the bed becomes depleted of the cohesive silts, and the stream area will then acquire a wide and shallow section, and relatively a greater bed surface for transportation; the velocities, even with minimum discharges, will always be sufficient for moving sand grains.

(8) It is possible to build a diversion structure, with stream approach control, such that it will exclude the traveling bed load automatically, and this would eliminate the necessity for cumbersome sand-trapping basins (the word, "desilting," is not truly applicable) and desludging operations. Such a structure will save money in the first cost of construction and in the costs of operation and maintenance.

(9) Construction of the new head-gate will probably not proceed before the Hoover Dam is advanced sufficiently toward completion to provide effective control of up-stream floods. In the meantime, competent investigation and research on problems pertaining to the silts and sands in transportation, especially within the range of those discharges expected in the future, and on the efficiencies of desilting that can be obtained, will eliminate much of the present guesswork and will enable development of the works to proceed on sound lines, from established findings. Certainly, this is a justifiable aim in view of the permanence and importance of the control structure.

ACKNOWLEDGMENT

DISCUSSION

C. E. Grunsky,[33] Past-President, Am. Soc. C. E. (by letter).—It is with satisfaction that the writer notes a reviving interest in some of the larger problems of the Colorado River. Of this reviving interest, this paper on a method of freeing the river water of a large proportion of its bed load of silt at the head-works of the proposed All-American Canal, gives evidence. The subject is certainly one which merits the careful attention and study of the Engineering Profession. The magnitude of the problem has gone unquestioned and yet, to the present time (1933), how little is known of the physical characteristics of the silt particles, carried by the waters of the Colorado, which are to be handled! What are their dimensions? What shapes predominate? How much colloidal matter is with the silt? It is indeed refreshing to have the author emphasize the magnitude of the bed load of the Colorado. In this matter, however, the writer is not in full agreement with Mr. Rothery. He is willing to concede, and in an earlier paper[34] has endeavored to demonstrate, a large bed load, but found nothing to warrant the author's intimated conclusion (see heading "The Bed Load") that the bed load of the river exceeds its suspended load.

The writer is in full accord, too, with the author's contention that there will be silt problems at points of water diversion below the completed Hoover Dam, even if in the course of time these may be greatly simplified. The writer is, for example, still among those who do not understand the reason why the Metropolitan District did not take advantage of the desilted supply of clear water which will be available at the Hoover Dam, instead of selecting a diversion point for domestic water far below it, where the engineer will have to contend with all the annoyances of a turbid river supply.

The writer does not care to enter upon a discussion of the merits of the author's plan for ridding the water of its bed load at the head of the proposed All-American Canal, but in this connection, would merely say that if the bed load can be eliminated, the problem of canal operation and maintenance becomes relatively simple. This is due to the fact, well established by all the available observations, that Colorado River water, entering a canal from the river, will carry its suspended load practically without change throughout the length of the canal. Any device for removing or, at any rate, for greatly decreasing the bed load, should be simple and relatively inexpensive. The nearer it can be kept in design to a sedimentation basin with suitable sluicing facilities the better.

Ivan E. Houk,[35] M. Am. Soc. C. E. (by letter).—The author has contributed a comprehensive, timely, and interesting review of the many important problems involved in the measurement and control of silt transportation in the Lower Colorado River.

[34] "Silt Transportation by Sacramento and Colorado Rivers and by the Imperial Canal," by the late C. E. Grunsky, Past-President, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1124 *et seq.*

[35] Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

Many of the data used as a basis for his discussions are of an approximate nature. Consequently, his conclusions can only be considered approximate. Probably the greatest value of his review is the emphasizing of the complexity of the silt problem and of its importance in future river-control work.

It is indeed unfortunate that accurate data are not available to show the average depth of periodic flood scour in the section of the Colorado River under discussion. Isolated observations of scour may be very misleading as regards representative conditions in a 300-mile stretch. River gauging stations are usually located at cross-sections where the stream is more or less contracted in width. Therefore, depths of scour observed at such stations usually tend to be greater than the average rather than smaller. Any computation of bed load based on an estimated average depth of scour is nothing more or less than a pure guess. It may be several hundred per cent. in error in either direction.

The writer believes that the author's guess of a spring flood bed load equal to twice the estimated annual suspended load is much too large, instead of being conservative as the author concludes. It is understood that river-bed excavations at Hoover Dam show that the depth of periodic scour in Black Canyon has been less than was formerly supposed. Actual measurements at other locations might show similar conditions. In order to make a fairly accurate estimate of the average depth of periodic flood scour in the river channel above Yuma, Ariz., it would be desirable to have detailed cross-sectional measurements during flood periods at locations about ten miles apart along the entire length considered, as suggested by Mr. Rothery. Even if satisfactory information were available regarding the average depth of scour, it would not be possible to make an accurate calculation of the total bed load, since a large proportion of the scoured material undoubtedly is carried in suspension. The estimate of total bed load based on an average depth of scour would necessarily have to make proper allowances for the suspension factor.

In rivers flowing through gravel and boulder formations undoubtedly there is a definite boundary between suspended and bed load silt. Such a condition may exist, temporarily, in some sections of the Lower Colorado River, at times when the erosion is deep enough to reach coarse gravel or boulder deposits. However, it is probable that during the whole, or, at least, during the greater part of the Lower Colorado River floods, there is a gradually increasing thickness of the mixture of solid particles and water near the bed of the river, rather than a definite line of demarcation. This is indicated by the difficulty in finding a solid bottom while making soundings during flood periods. The writer has experienced such difficulties in gauging floods in rivers flowing through much coarser materials than those characteristic of the Lower Colorado.

In measuring the silt content of the Colorado River flow at Yuma, approximately one-third of the samples were taken as close as practicable to the bottom of the river. Consequently, it is believed that the estimated silt flow based on the Yuma measurements includes a large proportion of the material eroded along the bed of the river at up-stream locations, material considered by the author as making up an unmeasured bed load flow.

The accurate measurement of silt flow is always a difficult matter, whether the material is moving in suspension, by saltation, or as a bed load. The writer cannot agree that where samples are taken near the bottom of the river, with the sampling bottles pointed up stream, the "increased percentages are properly part of the unknown bed load." Holding the bottles in such a position naturally results in catching more solid particles than are actually present in a given volume of flow. Such results cannot properly be used in calculating the silt load of the stream on the basis of a current-meter gauging of discharge. In order to determine the correct proportion of silt present in river flow it is necessary to adopt some method of segregating actual samples of the flow instantaneously at different locations in the cross-section, such as a long cylinder, open at both ends, placed in a direction parallel to the lines of movement and arranged so that the two ends of the cylinder, or the two ends of a central section thereof, can be closed simultaneously. A silt sampler was developed to operate in this manner.[36]

The author is undoubtedly right in his conclusion that "both suspended and bed loads will be present in the curtailed river flows below the Hoover Reservoir." However, his expectation that the suspended loads will "decrease in extent to almost negligible quantities as the regimen of the stream becomes stabilized" may or may not be fulfilled. As soon as Hoover Dam is put into operation, cloudburst occurrence, resulting cloudburst erosion, and details of surface geology on the tributary drainage areas below the dam will become important factors as regards the character and quantity of solid materials transported by the regulated flow. The writer is not familiar with the surface geology of the drainage areas of the Lower Colorado River. If there are large areas of extremely fine surface silt deposits in the lower tributary areas, and if cloudburst rainfalls happen to fall on such deposits, large quantities of material will certainly be eroded and washed into the main channel and will tend to keep up the turbidity and supply of suspended material.

The construction and putting into operation of the Elephant Butte Reservoir in New Mexico changed the soil transportation problem of the Rio Grande at El Paso, Tex., from what was essentially a silt problem to what is now essentially a sand problem, due to the fact that the tributary drainage areas below the dam are covered with sand and gravel deposits rather than with fine silt or clay deposits. The change would have been quite different if the Rio Puerco, of New Mexico, had joined the Rio Grande below Elephant Butte Dam, instead of above it. The Rio Puerco flows through deep and extensive deposits of fine silt. Its flow contains large quantities of silt during normal stages as well as during flood periods. A detailed study of surface geology, cloudburst occurrence, and cloudburst erosion on the tributary drainage areas of Colorado River below Hoover Dam would undoubtedly aid in formulating accurate predictions regarding the character and extent of the silt load to be expected after the reservoir is put into operation.

---

[36] "Silt in the Colorado River and Its Relation to Irrigation", by Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., *Technical Bulletin 67*, U. S. Dept. of Agriculture, p. 12.

H. M. Rouse,[37] Assoc. M. Am. Soc. C. E. (by letter).—An opportune and valuable study has been made by the author, indicating the need of drastic changes in the original published plans of the desilting basins for the proposed new Imperial Valley Diversion Works. He emphasizes particularly the large quantity of bed sand present in the river flow, which can best be handled by methods that differ from those used in handling the silt or suspended load.

The bed sand should be diverted neither into the Main Canal nor into desilting basins unless it may be proved by various experimental models of the diverson works that it cannot be separated and caused to flow continuously back into the river. Mr. Rothery's suggested plan for this part of the diversion works is a fine basis for beginning experiments.

The writer realizes from experience on the Imperial Valley Canal System, that bed sand is the most troublesome and costly factor in canal operation and maintenance, but believes that the suspended load, or silt, should also be removed, and that there will be enough of it in the future to warrant the construction of desilting basins. Although ranchers of the present irrigated area do not agree as to the value of the silt on the lands, a large majority believe it has little or no value as a soil renewer, and that it is a detriment to many crops.

The removal of bed sand will decrease greatly the cost of lateral canal cleaning in the present irrigated area. Silt removal will further decrease that cost and will stop the growth in the size of the unsightly banks or levees of the canals caused by cleaning out the silt and sand deposits. Bed-sand removal will allow of the installation and successful operation of underground pipe-line water distribution systems on the ranches, which are not now feasible on account of lack of slope or opportunity for sluicing the pipe lines. Silt removal will allow the use of pipe lines on very light slopes, or on whatever slopes clear water requires.

Possibly bed-sand removal will not require additional structures for slope control in the existing canal system, while silt removal will probably require some construction for slope control or against bank erosion, or both. However, this construction will come gradually and, in some cases, will permit of improvements in operating conditions. Furthermore, the slope control may be obtained in many cases at the time of building more diversion structures, which will be required from time to time as the lands are subdivided into smaller units.

The writer believes that the desilting basins are needed, in addition to the desanding works. However, the location for the desilting basins can be chosen where the large areas (which the author rightfully emphasizes are needed) are available without expensive quarrying in the mountains or expensive foundations in the river bed. This points to a location below the proposed diversion works where the Main Canal location begins to swing away from the river; or in the vicinity of Araz Junction, Calif., where the location is again near the river; or between the latter and Pilot Knob, Calif., where the location of the Main Canal can be near enough to the river to afford ample slope for sluicing the basins.

---

[37] Engr., Colorado River Land Co., S. A., Calexico, Calif.

A main canal slope can be used which without altering the basic project scheme, will carry the silt to the desilting basins, and the basins may be designed, constructed, and operated, so as to leave any percentage of silt desired in the irrigation water for the stabilization of canal banks in the sandy mesa lands and for the enrichment of the lands themselves. Should it be decided to leave some silt in the irrigation water for the last-mentioned purposes, additional desilting basins can be built at the western edge of the mesa lands, to clear the water for use in the present irrigated area. The construction of the desilting basins away from the diversion works would allow more freedom in the design of the desanding works.

The construction and testing of models of the diversion works, with desanding and desilting devices, and of models of desilting basins, if not already done, are needed for the final design of the head-works. Model study is needed, especially for the following (referring to Figs. 5 to 8): (*a*) Determination of the minimum necessary distance from the up-stream edge of the horizontal partition, to the irrigation water-control gates; (*b*) thickness of the lip of the horizontal partition and the material to be used in its construction; (*c*) shape and length of the approach channel; (*d*) type and location of drift-handling booms, gratings, or machinery; and (*e*) avoidance of the formation of bars at the mouth of, or in, the approach channel with floods of varying stages and duration, since it is possible that provision of more flood-gates in the dam proper, with less resulting variation of stage during floods, may be found desirable.

The enemy of desanding or desilting, of course, is turbulence. The author refers to "a side offtake without under-sluices" as being an "effective selector of bed silt." The head-gate of one of the main canals of the present canal system is a particularly good example of this. Although supplied with raised flash-board "sill" or overpour control, the water diverted carries its proportion of the bed sands traveling in the Main Canal above the diversion.[38]

At a point in another of the main canals a structure was built which combined the purposes of a check or control structure in the Main Canal, a head-gate for another canal, and an important waste-gate. The placing of the waste-gates some distance up stream from the other gates and in the bed of the Main Canal, was seriously considered, with the idea of removing a large amount of the traveling bed sands with the water wasted at this point. Practical difficulties prevented such location, and the waste-gates were placed vertically below the gates of the irrigation water control, the waste water entering a tunnel, the roof of which is the floor of the irrigation water-control gates above, the tunnel emptying at the side of the combined structure. Turbulence in front of the structure causes the bed sands to be carried on with the irrigation water as was expected, the percentage of sand in the irrigation water and the waste water being practically the same. This is a case of take-off in a direct line with the Main Canal, and with under-sluices provided, although, of course, the under-sluices could only be used to the extent that water was wasted.

---

[38] Reference is made to Photograph B, Pl. 2, *Technical Bulletin No.* 67, entitled "Silt in the Colorado River and Its Relation to Irrigation," by Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., which shows the bed of the aforementioned canal below the head-gate.

One of the troublesome effects of bed sand in the main canals of the present irrigation system is the fluctuation of the discharge at one point, with no changes at the next control point above. This trouble is evidenced by increases and decreases of hundreds of second-feet in the discharge at key waste-gates, the change amounting to a maximum of 700 sec-ft of a main canal flow of, say, 5 000 sec-ft. For some time gauges were read on a stretch of the Main Canal, and these readings indicated a raising of the water surface, because of the bed sands being temporarily deposited; then they indicated a lowering of the water surface, releasing the water which had been temporarily "stored" by the building of the bed-sand "dam" in the bottom of the channel. In some cases, a cycle of one of these fluctuations would take place in 5 or 6 hours and, in other cases, the decrease might be slow and the increase very sudden, the cycle taking 24 hours, or more. Sometimes the increase only would be noted, the decrease presumably being hidden in daily water handling, or in a very slow decrease of some days' duration. In order to cover the great fluctuations caused by the bed sands, large waste-gate capacity and a great quantity of water are required in order to avoid fluctuations of delivery to main canals, laterals, and, thus, to irrigators.

Seasonal movement of bed sands in the Main Canal also causes trouble in the spring, the bed of the canal having been built up during the low period of flow in the winter. In the past, lack of free-board or slope (or both) has restricted free handling of the water, requiring that increases in the Main Canal discharge be made in small quantities to give the bed sands opportunity to move out and thus increase the water area of the canal. Similar bed-sand phenomena on the Colorado River are generally known; but the necessity is not generally known for the Imperial System to carry large waste-water reserves to cover large fluctuations, the sources of which are on the main canals themselves.

William T. Collings, Jr.,[39] M. Am. Soc. C. E. (by letter).—Interesting data on the problem of soil transportation have been presented in this paper. The author has provided a conception of the magnitude of the enormous quantity of material carried by the Colorado River, both in suspension and along its bed. This problem is one that has confronted engineers on irrigation projects in the Lower Colorado delta region for years, and much has been written on the subject. As the author suggests, a thorough understanding of these data is necessary by those engaged in the design of irrigation works on, or leading from, the river.

The writer is particularly interested in a consideration of the merits of a plan proposed by the author for eliminating the desilting basins shown on the

---

[39] Engr., Imperial Irrig. Dist., Imperial, Calif.

Government design by substituting a horizontal partition separating the flow to the head-gate structure. The author makes the following statement:

> "A diversion structure placed across the river normal to the stream, provided with such a partition and under-sluices, properly proportioned, will exclude, automatically, all the bed load and that part of the suspended load in the lower water that passes under the partition."

A number of questions arise as to whether this statement can be borne out in entirety in application to the head-works of the All-American Canal, considering factors of major importance, such as magnitude of the structure, fluctuating river flow, available sluicing heads over and above irrigation requirements on the canal at periods of low-river discharges, shoaling, dependability of operation, maintenance, etc.

Under normal or average conditions of river inflow to Boulder Canyon Reservoir immediately after the completion of Imperial Dam—and for the first few years of the operation of the head-works, and when power demands both on Hoover Dam and on the Canal System have not been fully developed—there should be no occasion for close conservation of sluicing water at the head-works. However, firm power from Hoover Dam has been based upon output obtainable in low run-off periods as determined by run-off records from the Colorado River over a period of thirty years or more. The same conservative principle should be applied in the design of desilting works as regards capacity for sluicing operations in anticipation of possible low-period discharges. The possible demand for diversion at Imperial Dam as of date of completion will be close to 12 000 sec-ft, taking into consideration water to the Yuma Project, present Imperial and Coachella irrigation demands, and power installation. Assuming a maximum of 3 000 sec-ft, or the normal head-gate capacity of one of the desilting basins as sluicing head, the river flow required at the head-works would be 15 000 sec-ft. Under full development of the canal project, the full capacity of 15 000 sec-ft for the first reach of the canal to the drop for the Yuma Project is anticipated. Sluicing head then becomes a quantity over and above 15 000 sec-ft. It can be seen that under conditions to be anticipated during periods of low-river flow, approaching those of firm power output at Hoover Dam, economy in sluicing head is a major consideration in design.

The multiple-basin plan seems to offer a more dependable and conservative design, from the standpoint of sluicing head, than that offered by the author. While no definite quantity has yet been determined as to the minimum required under the full capacity of diversion with the six basins in operation, the writer believes that 3 000 sec-ft would be quite adequate, if not much in excess of requirements under the heaviest silt content, in so far as cleaning of the basins is concerned. No doubt, larger heads will be necessary periodically to clear the river channel below the structure. Referring to Fig. 5 of the tentative plan shown by the author, using the width of 700 ft in the uniform approach channel and 8 ft as the depth of water in that part of the water cross-section above the horizontal division wall (or what might be called a "water splitter"), the resulting mean velocity of approach for

15 000 sec-ft of water becomes 2.68 ft per sec. Assuming 4 ft as a minimum depth of water below this wall, the water cross-section below the wall line produced and immediately up stream from the inlet to the under-sluices, is 2 800 sq ft. The mean velocity of approach in the full cross-section would be approximately at the location of the horizontal division (or about 0.7 ft above). The mean velocity in the lower part of the water section would depend somewhat upon the friction factor on the bottom of the approach channel, 1.7 ft being a safe minimum value to use. The mean velocity in the full water section would be approximately 2.4 ft per sec. Assuming that these velocities remain unchanged at the entrance to the under-sluices the discharge through the sluice-gates would be 4 760 sec-ft (neglecting the cross-section area of the longitudinal supporting walls and horizontal partition).

Considering inlet-gate capacity to the canal flume alone, the width of 700 ft, or 750 ft, as shown on the tentative plan, does not utilize all the 2.0 ft of head available. Using 0.6 ft as the approximate loss of head through trash racks, the net velocity head would be 1.4 ft, resulting in an intake velocity of about 5.75 ft per sec. Using 7.5 × 20 = 150 sq ft, as gate-opening, the capacity of one gate is 860 sec-ft, and the total width of the gate structure would be more nearly 400 to 450 ft. The increased velocities resulting in a narrowed approach channel would be reflected in the lower section of the water cross-section. To compare the sluicing head, consider a 400-ft width of channel, of the same water depth and like dimensions, 8 ft above the partition line produced up stream and 4 ft below this line, the respective areas in section would be 3 200 and 1 600 sq ft. The mean velocities in the upper and lower sections would be 4.68 ft and in excess of 3.0 ft per sec, respectively. The resulting mean velocity in the full water cross-section would be about 4.2 ft per sec. Assuming, again, that these velocities were unchanged at the entrance to the under-sluices, the quantity of water passing under the partition and through the sluice-gates would be, conservatively, between 4 800 and 5 000 sec-ft. This comparison is not a suggestion that the width of the gate structure and approach channel in such a design should be limited to the minimum required for the maximum diversion quantity. Provision for fluctuation in pond depth above the structure would be necessary to provide against overtopping the overflow weir at low discharges, which is accomplished by a widened structure. The writer believes that the multiple-basin plan would prove to be more economical in sluicing water by an amount of between 2 000 and 3 000 cu ft per sec, under normal or low discharges.

There will be long periods when the diversion and under-sluices would be passing the full river discharge, and during such periods, if likewise long periods of unvaried inflow to the canal were maintained, such a design as the author suggests might function satisfactorily in segregating the bed load of soil. There will necessarily be fluctuations of heads to varying demands from irrigation and power, and these fluctuations must be controlled by co-ordination of operation of the intake gates to the flume and the under-sluice gates at the ends of the sluice culverts. Under most favorable conditions, in order to maintain undisturbed velocities at the intakes it would seem that each battery of gates for the full width of the structure would have to be operated as a unit. Any material variance in discharge through adjacent sluice-ways would result in a disturbance in approach velocities creating turbulence sufficient to put large quantities of the heavier materials into suspension and carried above the partition and into the flume. As a matter of practice it would seem that such a co-ordination of gate operation, with about fifty gates involved, would be most questionable of attainment.

Considering the effect of longitudinal supporting walls and the installation of trash racks at the entrance to the sluice-ways, each of such walls becomes virtually a "water splitter" in a vertical plane. If the horizontal wall could be permitted a considerable over-hang up stream, these might have but little effect upon the approaching water velocities. No over-hang of the horizontal wall would be permitted up stream from or above the trash racks. Therefore, any over-hang must necessarily support the racks from lateral pressure. The cantilever action in the over-hang would limit its length to that of a short lip unless heavy beam reinforcement was added, which beam construction would be objectionable as an entrance factor. Submerged débris lodging against the trash racks above the under-sluices would, at best, be difficult to remove; but if lodged under any permitted over-hang it would be almost impossible to remove under flow conditions. It is thought that the combined effect of trash racks and vertical partition walls would be adverse to a continuous and unobstructed transportation to a free discharge of the bed soil.

Another serious consideration in the design of a structure of such proportions, particularly with a large number of gates, is the matter of maintenance. Accessibility to gates and sluice-ways in cases of repairs is necessary, and this with the minimum interruption of diversion and sluicing operations. The maintenance of the basin structure would be comparatively simple where it is possible to cut out one or more basins or sluice-ways without seriously impairing or interrupting the operation of the others.

The aggregate capacity of the tentative design for the dam and head-works by the Bureau of Reclamation is 259 000 sec-ft. It is unlikely that under regulated river flow the head-works will ever be called upon to utilize any quantity closely approaching that capacity. However, it is not unlikely that the river discharge at Imperial Dam will exceed, perhaps materially, 110 000 sec-ft prior to provision for other storage works below the Big Williams water-shed. From experience by the Imperial Irrigation District, the Yuma Project, and other agencies in dealing with the control of the Colorado River under flood discharges, it is hazardous to predict what may be the extent of shoaling and channelizing above any structure that tends to divide the flow of the river. It seems reasonable to believe that, under a sudden increase in the flow of the river from a comparatively low discharge to about 100 000 sec-ft, with a quickly receding river thereafter, that at times sufficient material would be deposited at the head of a trained approach channel to the diversion works to require removal before normal flow conditions could be restored, or at least to interrupt inflow to the diversion gates. In looking forward to the operation and maintenance of the head-works, naturally, the engineers of the Imperial Irrigation District are hopeful that the design eventually adopted will preclude any possibility of dredging operations.

At the time the location surveys were being made by the Bureau of Reclamation for the All-American Canal, the engineers of the Imperial District did some research work on certain of the main canals in determining hydraulic elements of flow. Of particular import was the adoption, as nearly as could be determined, of the proper value of the coefficient of n to be used in the design of canal sections. The canals studied were the Alamo Canal (the main canal through Mexico), at Alamo Mocho Station; the East Highline Canal at "B" Heading; the Central Main, Briar, and West Side Main Canals at the International Boundary Line; and the West Side Main Canal at what is known as the Drain Station.

In Table 1, the values of A, V, and Q were obtained from current-meter records of discharge and the values of p and r were computed. The slopes of the canals were determined by field measurements and C was computed from the Chezy formula: $V = C \sqrt{r s}$. The values of n were determined from a diagram of functions computed from Kutter's formula. Considerable thought was given in these studies to the determination of non-silting and non-scouring velocities.

At Alamo Mocho Station, the Alamo Canal is known to silt and scour more or less. No doubt, this explains the erratic values in Table 1 (*a*), which shows a very low value of n at medium discharges and high values at high and low discharges, when silting and scouring, respectively, occur.

Referring to Table 1 (*b*), it is to be noted that the results show a very consistent and relative increase of velocity, with the hydraulic radius. They also show a quite consistent value of the friction coefficient, say, a mean of 0.0185. In Table 1 (*c*), the variable n-values for flows between 100 and 400 ft per sec, are probably due to the effect of silting at low velocities. The mean value of n in Table 1 is approximately 0.020.

The West Side Main Canal just below the meter station at the International Boundary should not be considered typical of a non-silting and non-scouring canal. The sides and bottom of this canal show a hard and tight clay, and an eroded rough surface. This results in the unusually high coefficient of friction as evidenced by Table 1 (*d*).

At the Drain Meter Station, the West Side Main Canal is practically self-maintaining. What silting may take place at low heads is relieved when these heads increase, and no cutting of the banks takes place at maximum heads. It is to be noted in Table 1 (*c*) that the functions are quite consistently related through a range of flow from 450 to 650 cu ft per sec. The variation of Kutter's n is also uniform.

The Briar Canal functions under a light grade and comparatively slow velocities, which tend to permit the rapid deposition of silt under normal heads. The Briar Sluice at Birch Canal was installed after the meterings

*Sections considered non-silting and non-scouring.

listed in Table 1 (*f*) were taken. This canal should not be considered typical of those that are non-silting and non-scouring.

The action of bed silt is interesting in the fact that at times the meter gauges will indicate a smooth even cross-section and then, again, large holes are found across the bottom of the canal caused by a movement of the bed silt. It has also been noted that even where a canal has been considered self-cleansing there are times when large quantities of bed silt will move in and raise the bottom considerably. This will last sometimes for only a day or two and again for a period of several weeks. This movement of bed silt creates large fluctuations in canals of the size of the Alamo and makes it difficult to maintain a regulated flow.

From Table 1 it will be noted that these silt-laden canals of the Imperial System function under high velocities relative to earth canals. This is true in cases for discharges as low as 50% of the canal capacities. Close observations of the functioning of these canals under varying heads indicates that under flows exceeding about two-thirds of the full capacity, little trouble is experienced in the silting in or scouring out of the beds of the canals, particularly those operating under excessive grades. Relatively high velocities are required, also, to maintain movement of the bed load, which is often very erratic.

Information that is helpful in the consideration of velocities in a channel of approach to a desilting structure, whether it be to function automatically, by settling basins, or by mechanical means, might be gained from a study of Table 1. The writer is of the opinion that it would require a mean velocity closely approaching 4 ft per sec for an unlined channel of 15 000 to 20 000 sec-ft capacity, in order to keep the bed load of silt moving with a sufficient degree of uniformity. Mean velocities in excess of 4½ ft per sec would tend to turbulency. These deductions are also based on the results made from similar studies of the velocities in the Colorado River made by the Bureau of Reclamation from gauging records of the Yuma Project at the time the canal studies were made. If correct, these deductions would be adverse to the acceptance of eliminating entirely the basins in favor of under-sluice operation where so wide a channel is involved.

At the present writing (1933) engineers of the Yuma Project are conducting certain silt studies at the project diversion at Laguna Dam. Most certainly, as the author suggests, the correct solution of the problem in the design of the Imperial Diversion warrants sufficient research work along this line.

R. F. WALTER,[40] M. AM. SOC. C. E. (by letter).—The author has submitted a valuable and opportune paper, which is of particular interest to the writer due to his connection with the U. S. Bureau of Reclamation, to which organization has been entrusted the duties of designing and constructing the works discussed. The structure referred to, and for which tentative plans are shown in Figs. 5, 6, 7, and 8, has been officially designated, Imperial Dam. With its appurtenant works, it will constitute the diversion and desilting structure for the All-American Canal. The design and construction of these works now (1933) await certain legal actions and the appropriation of the necessary funds by Congress.

---

[40] Chf. Engr., Bureau of Reclamation, Dept. of the Interior, Denver, Colo.

In his acknowledgment, Mr. Rothery makes reference to certain material for the preparation of Figs. 5, 6, 7, and 8 of his paper, as having been made available through the writer. The material referred to is a drawing showing a desilting plan very similar to that shown by Fig. 8 of the author's paper, but with the sand sluice omitted. Reference is also made in the paper to a cost of $3 375 000 for the proposed desilting works. Both the cost estimate and the drawing referred to by the author, are part of a report by one of the engineers of the Bureau of Reclamation on the All-American Canal investigations carried on during 1929 and 1930. The report is dated May, 1931.

While it was doubtless not the author's intention to give the impression that the plan furnished him or the estimate of cost were other than tentative, still the impression might readily be gained that they represented works designed and approved for construction. This is not the case since the plan which was the basis for the estimate is of a very preliminary and tentative nature.

The investigations leading to the report of May, 1931, were conducted in the same manner as other similar investigations of the Bureau of Reclamation. Only sufficient field surveys and office designs were made to permit of reasonably dependable estimates of cost being prepared. For such a preliminary report and estimate it was obviously not practicable to go carefully into the design of a structure of such uncertain operating characteristics. Instead, and as a basis for a tentative estimate of cost, a sketch plan was made for a structure somewhat similar in its operation features to the Laguna Dam at the head of the Yuma Canal. The desilting plan at this dam, while being far from ideal or of great efficiency, has served the Yuma Project for many years.

Reference is made by Mr. Rothery, to the methods used by the Imperial Irrigation District to prevent, in so far as possible, the bed load of the Colorado River being carried through the canal. This has proved to be an expensive undertaking and it is known that the District's officials consider even the Laguna Dam method of silt removal a great improvement over the method used by the District, and by comparison quite satisfactory and economical in operation.

Probably one of the most objectionable features of the desilting basin at Laguna Dam is the necessity of having to interrupt irrigation deliveries during the sluicing period. This is necessary because there is only one basin and no by-pass. To obviate this necessity, and in order to carry the greatly increased capacity of the All-American Canal, six desilting basins were tentatively proposed for construction at Imperial Dam. With this system the full capacity of the canal could be passed slowly through any five basins while the sixth was being sluiced of its accumulation of sludge without interrupting full canal diversion. For less than full canal capacity (which will doubtless be the usual operating condition for many years after the canal is put into operation, and even then for the greater period of each year) less basins could be utilized, but probably a better plan still would be to utilize five basins, in which case the flow through the basins would be at a reduced rate, permitting better settlement conditions. For velocities of less than 0.5 ft per sec appreciable quantities of materials that are on the border line between bed and suspended load should settle out in the basins.

Whether quantities of suspended material, such as would justify the large basins tentatively considered, will settle out with the depths necessary in the basins and at velocities of flow required, should be known definitely when the very carefully planned investigations now being carried on at Laguna Dam are completed. These investigations should demonstrate quite definitely the efficiency and economic practicability of this type of basin. Due to the availability of suitable materials—earth for the embankments and rock for rip-rap—the excess cost of this type of desilting works will not be as great as might at first be assumed, because of the long embankments required in the construction of the basins, compared with the cost of the more simple sluicing structure, shown in Figs. 5 and 6. However, should the present investigations show that no great efficiency is gained by building the large basins they should not be used.

It is not the writer's intention to enter into a discussion of the comparative merits of the desilting plan upon which the estimate of the Bureau of Reclamation was based, or of the simplified desilting structure suggested by the author, since certain important investigations being conducted by the Bureau which are expected to furnish the fundamental data for the preparation of final designs, have not yet been carried to such a point as would justify such a discussion. However, several different plans for the exclusion of silt from the canal, both bed and suspended load, have been, and are, being considered by the Bureau of Reclamation.

The general plans considered cover a wide range of construction, from the most simple sand-trap structure of unknown efficiency, to a comprehensive system of mechanical clarifiers of relatively known efficiency, such as are used in connection with municipal water purification plants and certain mining operations. The so-called vortex tube, with its various modifications, has also been given consideration for the removal of bed silt that it may not be possible to exclude from the head of the canal or that, for one reason or another, may reach the canal below its point of diversion.

The difference in first cost of the various plans considered is naturally very great and not directly comparable since the performance expected from each plan is quite different. One familiar with the silt problem of the Colorado River will realize at once that the cost of desilting works will increase rapidly with any requirement for increased efficiency in the removal of the suspended silt transported. The final choice of plan may not be based purely on first cost, or on operating cost, since the question of efficiency in operation and desirability as regards the quantity of suspended silt to be removed, may have a deciding influence in the choice.

Each succeeding year brings out more clearly the detrimental effects, to the present irrigated areas of the Yuma Project and the Imperial Irrigation

District, of irrigation with water containing large quantities of suspended and colloidal materials. Water users have been known to have closed their headgates and to do without water for limited periods, rather than to accept water especially heavily laden with fine silt. Whether it is economically possible to remove such materials or whether the construction of Hoover Dam, and possibly Parker Dam, will automatically correct this undesirable condition within a reasonable period of years, are matters for consideration.

The author's suggestion that the silt carried in suspension, during the early years of canal operation, will be of benefit to new land and lateral developments, and should be taken advantage of in connection with the development of new lands with sandy soil, may have some merit; unfortunately, however, it is not likely that any great area of the new sandy lands will have been brought under cultivation until after the stabilizing effects in the river shall have become felt and the quantity of silt carried in suspension will have been greatly reduced.

The writer is not in full agreement with the author on all the points discussed in his paper, but on one point at least he is in full agreement; that is, wherein he suggests that due to the permanence and importance of the control structure, competent investigations and research pertaining to the silt problem should be made so that as much as possible of the present guesswork will be eliminated.

In line with this suggestion the Bureau of Reclamation has already made an exhaustive research of published literature in this as well as in many foreign countries, in an effort to have available all data bearing on the silt problem. Access has also been had to many records and reports not available in published form. A bibliography of all such information has been prepared and is being added to as rapidly as new data become available.

Records have been kept of the quantities of silt carried in suspension in the Colorado River at Yuma, Ariz., for a period of more than eighteen years. Records of silt content at other points on the river are also available. These data as regards the content of suspended silt are considered quite adequate and dependable for making a comprehensive silt study. However, as regards bed load little definite information is available. Unfortunately, to date, no positive means are known to have been developed for measuring the bed load carried by streams. Study is being given this matter and plans are now (1933) under way which it is hoped will give reasonably accurate measurements of the quantity of total silt load in the Colorado River in the vicinity of the All-American Canal diversion. While positive determination of the bed load may not be possible, it is confidently believed that results can be obtained that can be used in the design of desilting works with greater assurance of reliability.

As stated previously, carefully planned investigations are being made at Laguna Dam in an attempt to learn additional facts regarding silt in the Colorado River. Analysis of the silt carried in suspension, as well as that deposited in the desilting basin, is being made. By use of the hydrometer method, determination is being made, not only of the particles susceptible of analysis by the ordinary sieve method, but of sizes down to those that require as much as two hours for settlement in still water in short tubes. It is hoped that determination can be made of the rates of settlement of the various sizes of silt particles, both in still water and at rates of flow such as may obtain in the All-American Canal, or in whatever type of desilting basin is under consideration.

A somewhat different and more comprehensive program of investigation and laboratory experimentation has already been outlined, but this can be undertaken only in case a special appropriation for the work is made available. During these investigations it is hoped to be able to ascertain with some degree of accuracy the quantity of silt that will be carried to the Imperial Dam, under flow conditions such as will obtain in the river after the construction of the Hoover and Parker Dams, and with the regulated flows required for diversion and sluicing the river channel and keeping it cleared of the sludge that will be turned back to the river from the desilting structure. Under regulated flow conditions in the river, discharges greater than 25 000 sec-ft will probably be of rare occurrence, within a few years after the completion of Hoover Dam. Discharges of less than this quantity, even with clear water released from the reservoirs, may not carry the quantity of bed load anticipated.

The author has called attention to an important problem in the development of the All-American Canal System, and one that must be given a great amount of consideration. Another problem, or rather a part of the same problem, that has been given little consideration in his paper, is that of the disposal of the sludge returned to the river from the partly desilted water diverted to the canal. This may prove to be one of the most discouraging problems of all. However, in some respects, the conditions will probably be favored by the natural occurrences in the sequence of operation of the Hoover Dam and the All-American Canal. For example, during the early stages of operation of the canal, only partial capacity will be required for the purpose of irrigation and power development along the canal. This will call for desiltation of a reduced quantity of water with a resulting decrease in the quantity of sludge returned to the river. Furthermore, a relatively large river discharge may be available, during the first few years of canal operation, for use in sluicing the sludge discharge down the river. Another factor that will also tend to diminish, possibly quite materially, the sludge return to the river below the Imperial Dam, will be the construction in the river of this dam, the crest elevation of which will probably be nearly 25 ft above the present elevation of the river bed. The dam will create a temporary reservoir of appreciable area that will act as an effective settling basin during the early period of canal operation. On the other hand, it may be that during the first few years of river re-adjustment, after completion of the Hoover and Parker Dams, relatively high river discharges will still occur and even greater quantities of bed load materials than at present will be carried to the Imperial Dam.

HARRY F. BLANEY,[41] ASSOC. M. AM. SOC. C. E. (by letter).—The author has contributed a valuable paper on the subject of silt transportation. It is of special interest at this time because large sums of money will be spent during the next few years building structures to utilize the waters of the Colorado River, and the success of such projects will depend primarily upon whether diversion works are properly designed for silt control. The paper brings out clearly the fact, not always recognized in the past, that the bed load in the river is large and that the control of bed silt is one of the major problems confronting the designer of head-works on the Lower Colorado.

In 1926, the late Samuel Fortier, M. Am. Soc. C. E., and the writer prepared a report[42] on a series of silt investigations on the Colorado River, conducted by the U. S. Department of Agriculture from 1907 to 1925. One of the surprising facts revealed in these studies was that the suspended silt load in the river at Topock, Ariz., was considerably greater than that at Yuma, Ariz., 206 miles farther down stream. Comparison of the normal annual load at Topock with that at Yuma, exclusive of the Gila River, indicated that 36% of the silt at Topock either passed Yuma as bed silt or was temporarily deposited in the channel or flood plains above Yuma.[42] An investigation by Mr. C. S. Howard[43] confirms this finding. The average of his results for a 3-year period ending September 30, 1928, shows that the annual suspended matter carried by the river was 286 000 000 tons at Grand Canyon, 231 000 000 tons at Topock, and 174 000 000 tons at Yuma. After applying a correction factor by estimating the inflow of the Gila River above the Yuma Station, these data indicate that about 34% of the suspended silt load at Topock became bed silt before reaching Yuma. The difference between the average annual quantity of suspended silt measured at the Grand Canyon and that at Yuma, exclusive of the Gila, is estimated as 72 000 acre-ft, based on the assumption that 12% of the silt load at Yuma comes from the Gila River,[42] and that the dry weight of silt is 85 lb per cu ft. Undoubtedly, most of this becomes bed silt.

Thus far, no method has been developed by which the volume of material moved as bed load can be measured. The aforementioned calculations may be a means of approximating the quantity of bed load carried by the river past the diversion works contemplated for the All-American Canal. The writer is of the opinion that as the river emerges from the canyon section, it is carrying its greatest load of suspended silt due to the steeper grades, higher velocity, and churning effects of the canyon section; then as the river flows on flatter grades below the canyon section the heavier silt is temporarily deposited and becomes bed silt, or rests on the bed of the channel until a flood carries it farther down stream. Many estimates have been made of the volume of silt transported by the Colorado River and some of them are shown in Table 2.

The author gives the reader the impression that "the traveling suspended load cannot be greatly reduced with the desilting basins." It is true that

desilting has not been so successful at the Rockwood Heading of the Imperial Irrigation District, due primarily to the fact that the river is not regulated and practically the entire flow is diverted into the heading at extremely low stages of the river. However, experiments made in 1918 by the Bureau of Agricultural Engineering on the efficiency of desilting at the head-works of Laguna Dam, indicated that the desiltation ranged from 33 to 72% and averaged about 57 per cent.[44] Raymond A. Hill, M. Am. Soc. C. E., also carried on experiments at intervals during several years, and he found that desiltation ranged from 18 to 70% with an average of 50 per cent.[44]

While the intake at Laguna Dam for the Federal Project at Yuma, is the most effective that has been installed to date on the Colorado River, in ridding the water of its heavier silt it is creating a soil problem that may be difficult to solve. By the desilting process the clays and colloidal material are separated from the sand in the silt and deposited on the irrigated land. This annual deposition is bringing about a change in the character of the surface soil, making it more sticky, more difficult to cultivate, and more impervious.

The writer believes that the term, "silt," is preferable to the term, "soil," in the title of the paper, since the term, "silt," is now more commonly used by engineers and is subject to less criticism by soil authorities than in the past.

CALVIN V. DAVIS,[45] M. AM. SOC. C. E., AND DIRK A. DEDEL,[46] ASSOC. M. AM. SOC. C. E. (by letter).—This paper describes excellent designs for structures to remove silt and bed load, which are appurtenant to the proposed Colorado

[46] Designing Engr., Ambursen Constr. Co., New York, N. Y.

River diversion dams. In view of the thoroughness with which the author has treated all phases of this problem, it is difficult to suggest basic improvements in his tentative plans. Several individual elements of the plans, however, may be discussed to advantage, owing to the fact that alternate designs capable of performing the same functions may be used.

In Fig. 6 (*a*) and Fig. 8 (*a*), the author has shown, up stream of the diversion works, intake tubes that consist of a floor and a horizontal partition supported by light vertical walls. These intake tubes are intended to convey a major portion of the traveling bed load to conduits which either pass directly under the dam and flume and discharge in the river down stream of the flume, as shown by Fig. 6 (*a*), or turn at right angles at the toe of the intake structure and discharge in the river below the main diversion dam, as shown by Fig. 8 (*a*).

The writers are of the opinion that while the intake tubes, as shown in Fig. 6 (*a*) and Fig. 8 (*a*), will trap most of the moving bed load there is the possibility that under certain flood conditions a part of this bed load may pass into the canal.

A modification of Mr. Rothery's intake design which the writers believe will, under all flood conditions, eliminate the traveling bed load and most of the suspended silt load before it reaches the canal, is shown by Fig. 9, which is a draft distributor devised by Mr. R. D. Johnson and the late Petrus Wahlman, M. Am. Soc. C. E. This modification merely consists of substituting a slot of the type shown in Fig. 9, in the top of the intake tube, for the horizontal partition and rectangular entrance as indicated by Mr. Rothery. The tube shown by Fig. 9 (*b*), is connected to a bed-sand conduit at the heel of the intake dam. This conduit is carried across to the heel of the dam in the main river section where its discharge into the river is regulated by sluice-gates (Fig. 9 (*c*)).

This arrangement would draw in from the top the entire bed load of sand, and most of the suspended load, with a minimum of disturbance. A model test,[47] reported by H. G. Acres, M. Am. Soc. C. E., indicated that water may be drawn into this type of tube in shallow rivers with practically no disturbance. The velocity through the slot, however, would be more than sufficient to draw in the traveling load of sand and most of the suspended silt. An additional advantage of this type of intake tube is that it eliminates all danger of river-bed erosion such as might occur under certain conditions at the mouth of a tube wth a rectangular opening.

If desilting basins are used the writers believe it more advantageous to locate the bed-sand conduit at the heel of the intake dam (such as shown by Fig. 9 (*b*)), rather than to locate it at the toe of the intake dam as shown by Fig. 8 (*a*) of the author's paper. In the arrangement shown by Fig. 9 (*b*), the intake dam and conduit are independent structures. There can be no uplift pressure under the crest and apron slab from the head-water and the flow in the bed-sand conduit does not come in contact with the buttresses and piers of the intake structure as it does in Mr. Rothery's designs. It seems to the writers that there is considerable advantage in keeping separate structurally, as far as possible, those parts of the intake that perform different functions.

---

[47] *Engineering News-Record*, September 10, 1931, p. 403.

The writers agree with Mr. Rothery's finding that the traveling suspended load cannot be greatly reduced with desilting basins. It is believed that the use of draft-distributor intakes (as described in the foregoing) would make unnecessary the use of these expensive basins. Further research along this line would be highly worth while and might result in large savings in cost.

FIG. 9.—PROPOSED MODIFICATION, DESILTING BASIN AND FLUME.

If desilting basins are used, however, there are several possible modifications of the author's designs which might result in both improved operation and savings in cost.

As Mr. Rothery has pointed out the slightest movement in a prism of water that has been stilled for the purpose of settling out the silt, will put this silt back in suspension. The gates discharging the water from the desilting basin to the flume (Fig. 8 (*a*)) might cause sufficient disturbance when in operation to put some of the sludge in suspension again even if these gates are in the most favorable position.

The writers believe that the alternate design for an outlet structure, such as is shown in Fig. 9, will eliminate any possibility of disturbance in the settling basin while the outlet gates are operating. This structure consists of a silt conduit from which the sludge from the desilting basins is discharged laterally into the river. The flow of this sludge into the silt conduit is controlled by gates leading from each basin at the bottom of this conduit. The flow of clear water from the desilting basin to the canal is controlled by a small gate structure on top of the conduit. In front of these gates are horizontal partition slabs supported by light vertical walls which are somewhat similar to those used by Mr. Rothery in front of the intake tubes. These horizontal slabs are intended to prevent the higher velocity adjacent to the gate from causing any disturbance in the desilting basin after the sludge has settled.

The flow through the silt conduit is controlled by outlet gates in the outer partition wall of a dam of the buttress type supported by a floor-slab. Two of the buttresses of this dam are continuous with the walls of the silt conduit, as shown by Fig. 9 (*a*) and Fig. 9 (*f*). This type of buttress dam has been shown for both the end of the desilting basin and the sides of the canal flume.

It is believed that the arrangement of the silt conduit shown by Fig. 9 will be more enonomical than the proposal to discharge the sludge from the desilting basin through conduits under the flume, as shown by the author. The expensive conduits are omitted, and only light paving is required for the bottom of the flume.

THADDEUS MERRIMAN,[48] M. AM. SOC. C. E. (by letter).—The subject of this paper is of great importance, and the author has forcefully presented the situation with respect to the "bed load." In 1930, the writer suggested[49] the view referred to by the author that the suspended load is only a part of the total and that the bed load carried by a flood is proportional to the bed volume scoured out.

Further reflection during the succeeding three years and a careful reading of the author's paper, including the discussions thereon, confirms the previous conclusion of the writer that,

> The bottom load carried per unit of time is equal to the volume of material scoured out per unit of length.

---

[48] Chf. Engr., Board of Water Supply, City of New York, New York, N. Y.

[49] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1142.

This theorem is a statement of the conditions that must obtain if the river channel is to refill itself while the flood is subsiding. Otherwise, the regimen of the river would be subject to constant and progressive change in proportion to the amount by which the actual conditions differed from those of the equilibrium which the theorem defines. The stability of the regimen between Black Canyon and Yuma is, therefore, evidence of the correctness of the proposition which, in connection with soundings and under the limitations stated[49] by the writer, furnishes a means of approximating the "bed load."

The completion of the Boulder Canyon Reservoir will greatly upset the equation of equilibrium in that no new material will be available to pass on down the river. Under the new conditions of reduced flood stages and uniformity of flow the regimen of the Colorado will at once begin to show marked changes which are not readily predictable, but which will be of the nature indicated by the author.

J. C. Allison,[50] M. Am. Soc. C. E. (by letter).—This paper is extremely interesting. Many articles and studies have been produced dealing with this subject. The excessive heights to which the great canals of the Imperial Valley are now elevated above the surface of the farming land, due to the deposit of silt, bear witness to the extreme importance of the problem. The financial statements of the Irrigation Districts of the Valley reveal the millions of dollars in operating cost traceable in greater part to the silt-removal items, and these tabulated millions are perhaps only a fraction of the grand total of costs to the farming community as a whole, chargeable to this one item. The writer has witnessed the progressive building up of the spoil banks along the canals with a continued sense of bewilderment as to what might be the final solution.

Exhaustive studies by the United States Bureau of Reclamation will undoubtedly reveal the best practical solution of the problem. Until these studies are completed it is difficult for an engineer to determine a plan that will come nearest to solving all the vexing questions that the "New Deal" on the Colorado River, with the Boulder Dam in partial control, has brought to the front. Already Mr. Rothery's paper has brought out what are perhaps the major questions to be solved. The writer's experience with this particular matter, prompts him to state the three major questions to be answered, all with the hope that the suggestion may be helpful in guiding the Bureau of Reclamation and the profession to the best practical plan.

I.—The greatest problem of all is the disposal of the sludge returned to the river from the partly desilted water diverted to the new canal at the proposed new Imperial Dam. In the writer's opinion, the volume of soil yet to be moved by the Colorado River below Boulder Dam can be measured only by the aproximate area of river soil deposited in the valleys of the Colorado between the mesa walls. This is limited, of course, to the uncontrolled sections of the stream bed. As the partly regulated stream seeks to establish its ultimate gradient and final position under the new operating conditions artificially set up in the creation and operation of the dam and its power plants, an unknown volume of suspended silt and bed load will continue to move down stream.

---

[50] Cons. Engr., San Diego, Calif.

If one can picture a gigantic task of finally disposing of all this deposit through the several hundred miles of unregulated channel between Boulder Dam and Imperial Dam in generations to come, the uppermost thought in one's mind is, what shall be the final resting ground for this uncalculable yardage? The answer is that there are only three ultimate places of rest large enough to accommodate the ultimate load: The Gulf of California, the Laguna Salada Basin, at the extreme lower end of the river, or the Salton Sea, in Imperial County, California. To move the sludge to any of these basins entails an expenditure of great volumes of transporting water. If the ultimate irrigation demand does not preclude this great expenditure of sluicing water, then Mr. Rothery's plan of selective separation of the lower third of the waters transporting the bed load, becomes one worth while studying and perfecting if possible.

On the other hand, if an economy in water is necessary in providing a sluicing head, then such a plan as is proposed by Mr. Rothery is barred from consideration. As a matter of fact, the entire plan of silt removal at the head of the canal, or at any point along the canal where the sludge is to be returned to the river bed, must be barred from consideration unless sufficient water can be supplied over and above the irrigation demand, to assure a volume and velocity sufficiently great to carry the bed load on through to one of the basins of rest mentioned.

There is apparently lurking in the author's mind the possibility that through some plan or other, these sluicing waters can be picked up and used farther down the river for irrigation below the Imperial Dam. The Mexican lands of the Lower Colorado Delta present the only area upon which this water could be used. Such a water supply, loaded to its maximum carrying capacity with bed load sand and silt, would not only be an unacceptable gift to Mexico but, if interrupted in its flow by diversion works in Mexico, would defeat the very purpose of its release at Imperial Dam.

The real answer to this particular problem lies in the determination, by the Bureau of Reclamation, of the quantity of water required annually to clear the river channel of its accumulation between Imperial Dam and the basin of final rest for the material. The surplus of water available during the early years of operation, before the period of full irrigation demand, cannot be considered and counted on too seriously in the design of the desilting works. The permanent volume of water available for sluicing purposes over and above the ultimate irrigation demands must be the quantity counted on to rid the river channel of its accumulated volume of sludge, because the bed load of sand picked up below the Boulder Dam and contributed to the channel by the drainage areas of Arizona and California tributaries to the river, will supply a load to be transported to the canal works of the Imperial Dam long after the peak irrigation dam is reached.

The plans for Boulder Dam provide a continued firm horse-power output of about 663 000 which will produce the 4 330 000 000 kw-hr of prime energy contracted by the Government for sale. Based on 83% efficiency and 10% maximum shortage, as estimated by the Bureau of Reclamation, this output will require an average volume ranging between 14 000 cu ft per sec and 17 500 cu ft per sec diverted continuously through the Boulder Dam power plant. According to the writer's calculations, the peak irrigation demand for the 2 100 000 acres finally to be reclaimed below the dam, will utilize this entire output from the power plants in the summer. In the winter, irrigation of the desert valleys of the Colorado River below the Boulder Dam will only use one-third of this power-development output of water; yet, unless and until other great dams in the canyons of the Colorado River are constructed, the irrigation demand cannot be equated with the power demand. Firm power in the aforementioned amounts as contracted for must be continuously developed in order to pay the costs of the dam within the 50-year period provided by law. Therefore, two-thirds of the winter output through the power plants must be continuously wasted. According to the writer's calculations, this seasonal wastage will amount to 3 544 000 acre-ft annually at Imperial Dam. The investigation being undertaken by the Bureau of Reclamation should determine whether or not this seasonal wastage is sufficient to clear the annual deposit of sludge from the river channel below Imperial Dam permanently. If it will not, the plan of utilizing the river bed as a depository for the bed-load soils taken from the All-American Canal, should be abandoned, except in the event of a re-arrangement of irrigation water delivery to Imperial Valley, as described under Heading III herein.

II.—Except for the "impatience and sentiment from the large agricultural communities of Imperial Valley," as pointed out by Mr. Rothery, it is doubtful whether the removal of all the silt in suspension will be found by the Bureau of Reclamation to be entirely justifiable, even if a plan can be devised to do so economically. When applied to the porous lands of the eastern mesa the clear water will not be as practicable, in canal operation or irrigation, as the silted water; when delivered to the lateral canals on the steep contours of the eastern and northern sections of the Imperial Irrigation System, the clear water will bring about compensative adjustments of canal grades, requiring many additional structures or concrete lining of the canals; also, more adequate drainage systems than are provided for in the existing financial plans. In the central and west central section of the Imperial Valley, where the canal grades are generally already too flat, a clear-water delivery would be extremely justifiable and beneficial if accompanied by adequate drainage provisions. A delivery of uniformly clear water for all sections of the irrigated lands to replace the silt-bearing waters abruptly, is not practical. It remains again for the Bureau of Reclamation to determine through its intensive study the extent to which the suspended soils can be removed justifiably. It appears to the writer that a less ambitious policy of suspended silt removal should be undertaken at the beginning, with provisions for later enlargement and perfection in various sections of the canal system, after a "cut and try" experience for a few years.

III.—The writer has in mind the great basin known as the Laguna Salada Basin in Mexico in the lower end of the Colorado River, as a final resting ground for the silts and bed sands of the river, rather than either the Gulf of California or the Salton Sea Basin. This selection is made because here all the sluicing waters used in clearing the channels above, can be recaptured and used for irrigation. As a matter of fact, with the establishment of a terminal reservoir at the Laguna Salada, no part of the river water will find its way to the ocean, because all of it can be recaptured through every month of the year except at times when more than 75 000 cu ft per sec are released at Boulder Dam.

This discussion is not the proper place to review the technical problems involved in establishing this reservoir, any more than to describe its characteristics briefly. At the extreme lower end of the river, just before the channel enlarges to form the upper area of the Gulf of California, the high waters of the river sometimes overflow and back up to the northward into the Laguna Salada, an extensive basin separated from the main delta of the Colorado by the Cucopah Mountains. The southern entrance to this huge basin is narrowed down to 5 or 6 miles. The basin broadens to the north between the Cucopah Mountains on the east and the Juarez or Peninsula Range on the west, finally terminating against a high mesa formation 8 or 10 miles south of the International Boundary Line. The floor slopes from 7 ft above sea level at the south to 17 ft below sea level at the north. This basin has been studied thoroughly, and it has been found that by blocking the southerly opening with a dike averaging 25 ft high, and by tunneling through 4 miles of the mesa formation at the north, a huge reservoir can be created, with drainage wasteways both at the south into the Gulf of California and at the north into New River and the Salton Sea. When the floor of the reservoir is desalted and the area reduced and deepened to save unnecessary loss of water by evaporation, the reservoir will still have a holding capacity of from 4 000 000 to 5 000 000 acre-ft of water.

A flood channel connecting the river through its delta with this reservoir entirely by gravity can be built by the two Governments under their agreed plan of international flood control on the lower river. This can be done with far less expenditure of money than such a channel can be built to the Gulf of California either along its present broken course, or along its abandoned channel to the east. The effect of this work would be to capture and store in Laguna Salada Reservoir all the water that will otherwise waste into the ocean. After the Boulder Dam is completed, this supply of water that cannot be regulated and saved by other means will amount to about 5 000 000 acre-ft per year. This wastage must continue until other dams the size of Boulder Dam are built in the upper canyons of the Colorado, in order to equate the power demand with the irrigation demand. Should all the water be saved by the simpler process of allowing it to flow by gravity into the Laguna Salada Reservoir, many millions of dollars will be saved, as other more expensive dams above will then not be necessary to save the winter discharge through the power plants for summer irrigation needs.

By this same process all international complications can be eliminated. The reclaimed waters can be delivered into the All-American Canal for all lands elevated in Imperial Valley below the sea-level contour. In a minor degree they can be used on Mexican lands along the border by gravity, where the elevations are not higher than 15 ft above sea level. The establishment of the reservoir would probably be the controlling factor in settling the question of the quantity of Colorado River water that Mexico is to have. As a matter of fact the recapture of waters, which otherwise would run perpetually to the ocean, will yield a supply more than sufficient to fill Mexico's demand if an exchange can be made of these waters for supplies delivered to Mexican lands at some point on the border higher than the 15-ft contour.

The cost of creating the reservoir with the delivery channel into it, the waste channels at both ends, and its delivery conduit northward, including the cost of removing the salt from the floor of the basin, could be met through a charge of 25 cents per acre-ft for the water delivered from this storage through a period of 50 years. With its creation, no economy in the use of channel-sluicing waters at any time of the year would be necessary at Imperial Dam. As the floor elevations are raised through the deposition of silt, in the reservoir, the water level would be raised correspondingly. Due to the excess grades in the river channel constructed to the reservoir, this raising could go on continuously by raising the channel banks and the supporting ground along the entrance channel with the silt dredgings taken from the channel. The very size of the reservoir itself, almost completely surrounded by mountains and high mesa plateaus, affords a suitable resting ground for Colorado silt, in all the years to come.

S. L. ROTHERY,[51] M. AM. SOC. C. E. (by letter).—The questions cited by Mr. Grunsky, as to the physical characteristics of the Colorado River silts, need to be answered by research as a first step in attacking the problem, the magnitude of which, he states, is unquestioned. Acceptance of a difficulty without seeking its analysis is contrary to engineering principles. Suggested answers to unexplained riddles often present themselves to the questioning mind, but the light of research is wanted in order to reject or verify suggestion.

The riddle of the turbid flow problem appears to be: Why do the suspended silts maintain general uniform distribution through a flowing cross-section, the charge or percentage of load remaining practically unchanged to any distant down-stream point?

A suggested answer may be reasoned from the studies before referred to[22] contrasting the shapes of silt particles to those of sand. Professor Terzaghi states that even a high-powered miscroscope does not discern the constituents of "micro-mud" (fine silts), but claims that their scale-like property is supported by many proofs, some of which are stated in the aforementioned studies. It is somewhat disappointing that none of the discussers gave new light on the physical difference between silts and sands, particularly as regards their carriage in stream flow and their characteristics of deposition in quiescent water. Partial settlement will be of little help in removing the turbid appearance in the first years following the storage behind the Boulder Dam; however, the relative volume of finest silts remaining in the 250 miles of river channel down stream, is so small in comparison to the present annual suspended load, that the question is again raised as to whether great desilting basins are really required.

---

[51] South Pasadena, Calif.

In explanation of the small remaining volumes, it must be remembered that the origin of the fine silts is above the Boulder Reservoir, a function of which is to trap the present annual quantities of 90 000 to 110 000 acre-ft of suspended silts. The Imperial Diversion will be 293 miles below the reservoir, and the river-channel area in this length is about 31 000 acres, according to U. S. Geological Survey Topographic Sheets. The effect of raising the water surface at the diversion structure and also at Parker Dam, will be to subject only a part of this length and consequent area to the degrading process, before the ultimate new gradient is attained, say, to 250 miles and 25 000 acres. Should the ultimate maximum recession be 25 ft, the mean at $12\frac{1}{2}$ ft would give a product of 312 500 acre-ft to be removed in, say, 10 years, one-third (34%) of it being the "fines". Then, again, since only one-fourth of the annual flow is diverted, the future turbid problem appears to become so greatly reduced that it seems reasonable to expect a noticeable improvement in the clarity of the flow soon after the Boulder Reservoir is in operation.

A careful investigation of the silts in the flowing canals was undertaken by the Department of Engineering of the State of California in 1918–19.[52] Quoting from this report:

> "By far the greater part of the total silt in suspension in the Colorado River and the irrigation canals is fine material that passes the 280-mesh per inch screen, * * * this material was in all cases found to be equally distributed throughout the vertical for all velocities under which tests were made, including mean velocities of less than one-half foot per second in small ditches. * * * The silts of the Colorado appear to be comparable to those of the Nile in degree of fineness, but they are much finer than those of the rivers of India."

Silt research on the Nile,[53] showed that in the lowest one-third depth, where the river was 26 ft deep, about one-half the coarse (that collected on a No. 100 sieve) and of the fine (that collected on a No. 200 sieve) sands, were located. It was certainly not the writer's intention to infer that there was a definite line of demarcation between the silts and sands in the turbulent floods of the Lower Colorado River; but, in the expected future regulated flows, when the maximum discharges will be from one-half to one-third their former volumes, and where the stream regimen can be improved to avoid turbulent approach, most of the sands in transportation will be near to, and along, the bed, which will be about 12 ft below the water surface. If a structure divides the water such that the sands in the lower one-third of the stream section will be carried on through under-sluices, those grains diverted to the canal with the upper two-thirds, will amount to only a minor percentage of the entire sand load, and this percentage could be eliminated in sand-trap structures at appropriate wasteways.

---

[52] Seventh Biennial Rept., Dept. of Eng., State of California, pp. 117–120.

[53] *Minutes of Proceedings*, Inst. C. E., Vol. CCXVI, pp. 205–206.

The tributary streams and washes in the 293 miles will occasionally be a source of additional sand, and perhaps some fine silts, to the river. However, the discharges from cloudburst rains on these tributary water-sheds are far from being continuous inflows, and it is believed that the contributed water is only the equivalent of a few days' average flow of the main river.

Mr. Rouse believes that the desilting basins should be built in addition to the desanding works, and suggests certain locations other than at the diversion structure. In this consideration (and always having in mind the time of detention of the flow to precipitate the fine silts referred to in the foregoing quotation, which from years of experience on the delta is emphatically endorsed), the writer offers the following plan as best adapted to obtain a maximum clarity of water for the present ranchers and the beneficial effect of silty flow for the new lands to be reclaimed on the East Mesa:

(*a*) Obtain the best possible desanding by under-sluices in the diversion structure, and perhaps a sand-trap structure across the canal not too far distant from the main structure, making no attempt to precipitate the suspended silts;

(*b*) Construct separate stilling-basins for the Yuma Project, to desilt 1 500 sec-ft, at a suitable location to the head of the Yuma Main Canal and where the sludge can be sluiced to the river, probably somewhere in the vicinity of Station 250 on the survey; and,

(*c*) Construct separate stilling-basins for the present irrigated lands of Imperial Valley, to desilt 5 000 (perhaps 7 600) sec-ft at about the west edge of the East Mesa, say at Station 2 990, sluicing along an obtained right of way to the Alamo Channel.

Then, whatever degree of desilting is attained by the type of basins devised, the problem is much simplified, due to the lesser volumes, than if one were seeking to detain 10 000 to 15 000 sec-ft, which has a velocity of $4\frac{1}{2}$ ft per sec; and a greater efficiency of desiltation could be accomplished at a minimum of construction and of daily operation costs. Furthermore, the long main canals crossing the porous soils to the East Mesa and on the Mesa, would receive the benefits of silty flow to help minimize percolation losses and contiguous areas of seeped lands.

It is true that an extra few hundred second-feet of sluicing water must be conveyed to the locations. The objection to the sludge going to Salton Sea is of growing lesser importance, since it has been argued that the suspended load is a decreasing one yearly and there is a relatively small total volume of the "fines" to be removed below the Boulder Reservoir.

Should the present lands of Coachella demand clear water, a smaller pondage could be provided near Salton, Calif., sluicing to the Salton Sea at about Station 4 200 on the Coachella Canal where the velocity is only 2.7 ft per sec.

The writer admits, and expressly stated in the paper, that the figures used to present a viewpoint of the bed load, were necessarily assumptions. His claim to being conservative in the volumes deduced can be re-stated, since in one instance a scour depth of only 9 ft was used, and, in the second instance, only 50% of the 300 miles in length were taken to allow for "deeps" and alternate "shoals". Both instances produced a removal (during a few weeks' time) of soil greater than the estimated yearly suspended load.

When excavating for the foundation of Boulder Dam, where the low-river water surface is at Elevation 645, a piece of sawed 2 by 6-in. board was found firmly embedded in gravel at approximately Elevation 595. The difference of 50 ft is indicative of deep scour. Reference has been made to the deep scour at Yuma,[13] and the writer recorded[54] a scoured depth of 20 ft on the delta on a rising flood, when the discharge was only 60 000 sec-ft and when the metering cableway was swept away in the flood. This flood increased to 110 000 sec-ft without any further raising in elevation of the water surface, indicating a still greater depth of scour. It must also be conceded that the distance of 300 miles is shorter than that in which the scoured material has been excavated and removed by the gradual rise of the spring flood.

The writer is not alone in pointing to the indications of this voluminous bed load. In 1930, Thaddeus Merriman, M. Am. Soc. C. E., stated[55]:

> "In any event, indications are that the volume of this [bed] load, when determined, will prove to be substantially greater than the suspended load which is now known within reasonable limits."

Mr. Merriman now confirms his previous conclusion. Mr. Blaney also makes a reference to the fact that there has been lack of recognition of the greatness of the traveling bed load. Such statements are of great value and will help engineers to realize the magnitude and the problem of the bed load, which the writer has endeavored to feature a number of times since 1921.

It was not the writer's intention that his paper should have been taken as a criticism of the tentative plans of the Bureau of Reclamation. During years of experience on the delta, he observed instances of scour, of deposition, and of suddenly changed river courses that seemed incredible to account for, until familiarity with the region and its disemboguing mud torrent provided a logical reasoning for what at first were surprises. He is convinced that the valuable estimates of soil transported as "silt in suspension", comprise only a part of the story. The silt problem of the Lower Colorado River has always been of absorbing interest, which has been responsible for much personal research and deduction. In submitting this paper, spontaneously written in a few days, the writer now believes that his presentation as to (*a*) a large bed load, and as to (*b*) the feature that its removal can be effected with the usual under-sluices while it is practically impossible to remove the turbid condition of the flow for great volumes of moving water, stress the fundamental principles of the problem.

---

[54] *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1417.

[55] *Loc. cit.*, Vol. 94 (1930), p. 1144.

Few engineers experienced on the Lower Colorado River have voiced their findings of silt characteristics. Realizing the importance of the subject for determination by specific research, in the "Synopsis" of the paper, the writer invited the publication of such research and the pooling of available knowledge. It is refreshing to know of the important investigations now in progress, referred to by Mr. Walters.

The psychological effect of expensive desilting basins is promissory of clear water to the canal systems; the writer had endeavored to show that this result is economically unattainable, since turbidity is produced by the "fines" (silts passing a 200-mesh sieve, and not susceptible to rapid deposition). The excessive "muddiness" of the water is the reason for the so-called desilting basins; yet only a fractional part, if any, of these excessive volumes of "fines" would be removed by the basins.

The reduced silt content, referred to by Mr. Blaney as about 50%, at the Laguna Dam Diversion to the Yuma Project, is suggestive that the multiple-basin plan will be equally effective for a diversion ten times greater. This may or may not be true. As the "fines" are not removed by the retarding basins, it may be preferable not to remove the coarser silts in carriage in suspension, in order to help guard against producing the objectionable sticky cultivating soil developing on the Yuma Project. In comparing efficiencies of proposed desanding basins with those of suggested under-sluices for eliminating sand in the approaching water cross-section, it would seem important and desirable to consider this precaution, the ideal requirement being to eliminate such sufficient part of the traveling sand as will suffice to prevent sand blocks occurring in the Main Canal. This is probably a matter of practical judgment from noting similar conditions and treatments on other great world projects.

The Sarda Canal, in Northern India, designed to carry 9 500 sec-ft, takes off from the Sarda River which "carries immense quantities of coarse silt during the flood season, and it was feared that in spite of all precautions, a considerable quantity would pass into the canal."[56]

The Sarda diversion structure is a side offtake "consisting of 16 bays of 20-foot spans. There is a masonry sill curved up stream to give a stream-line entry and thus avoid eddies which might cause silt to be picked up from below." The contiguous river sluicing sill or apron is at a depth of 6.75 ft below the masonry sill. Behind the sill are rising steel gates, which are usually lowered to permit the passage of top water over them into the canal. It is reported[56] that the canal head is working admirably; it excludes all heavy silt, and only the fine silt in suspension, which is useful for forming water-tight berms, is carried into the canal.

If eddies can thus be prevented by combining a stream-line entry design to the sills of the diversion gates, the horizontal partition may be shortened in length to its remote up-stream edge. It has been stated that the under-sluice passages would choke with submerged driftwood. Analyzing this possibility, the Boulder and the Parker Dams will trap such wood, and any occasional pieces brought into the approaching stream by intervening tributaries with cloudburst run-off, could be found and removed by the regular inspection and duties of the gate operators. Access to the passageways must be provided in the design; a tentative idea is suggested in Fig. 10.

---

[56] *Minutes of Proceedings*, Inst. C. E., Vol. 23, 1931-32, pp. 7-8.

Mr. Collings has estimated that 4 700 sec-ft of sluicing water would be the flow through the suggested under-sluices, and believes that 3 000 sec-ft would be adequate if the multiple basins were adopted. The flow through the under-sluices should be controlled by outlet gates, and would be variable depending on the traveling bed load and on the seasonal demand for the diverted water.

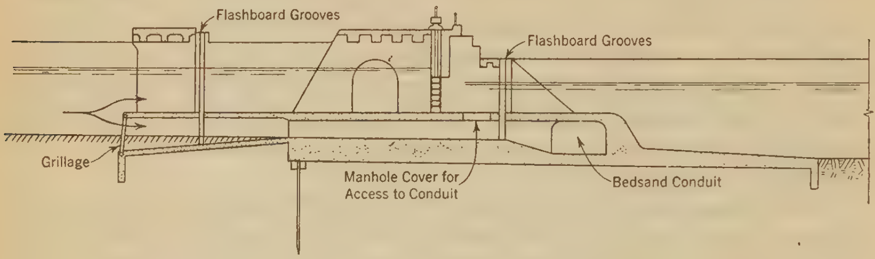

Fig. 10

For one or more decades after the Boulder Reservoir is first put in operation, a major part of the annual flow of the river will pass the diversion structure. The Yuma and California projects will use about 5 000 000 acre-ft annually, while the yearly run-off of the river varies between 9 000 000 and 25 000 000 acre-ft. Therefore, the question as to whether a few thousand second-feet of surplus water can be made available for the requirements of sluicing flow need not be raised for many years; nor will the market for the potential hydro-electric power be developed toward its ultimate capacity for a long period, to require conservation of all available water.

The writer purposely refrained from venturing into the field of probable effects that may be produced in the lowest reaches of the river by the unwanted sludge discharged through the sluices. Wishing to concentrate attention to the problem of effecting its separation from the diverted canal water is the reason for not making the matter of sludge disposal a feature of the paper. However, he is glad to see the point raised in the discussion.

In the river bed immediately down stream from the diversion structure, deposition of the surcharge of soil above the capacity soil load of the diminished flow may be expected to produce unstabilized gradients and may cause some expenditure for removing any adverse condition against the down-stream toe of the Imperial Dam, resulting from this deposition.

If the sluicing water and by-passed flow for other users of established water rights, are limited to minimum requirements, the usual stream to be expected would be reduced from its former river magnitudes that were laden with silts and sands originating in and above the canyon section of the watershed, to the comparatively small volumes of flow sufficient for a large-sized canal, and carrying a capacity soil load which originates in the 250-mile length below Boulder Dam. The aggregate available area contributing to this soil load, has been stated as about 25 000 acres, from which on an assumed 10-year period for removal, an averaged annual volume of 31 250 acre-ft is estimated; such a quantity is relatively insignificant when compared with the present vast soil volumes annually lodged on the lower delta. Therefore, there should be little apprehension there, as to the future soil quantities that may be expected, during the life of the Boulder Reservoir; and if the flow is occasionally increased to quantities above these minimum requirements, the ultimate soil volumes to be removed are not changed, and the sluicing soils may be insufficient to contribute capacity soil loads, whence varying degrees of turbidity and bed load are quite as likely in the lower river regions in the future with the lesser stream flows.

The failure in 1931 of a deep steel sheet-piling sea-wall, retaining a fill dredged from the estuary of the Los Angeles River produced investigations in which it was essential to know the correct unit weight of the fill. A mechanical analysis showed fine silts to predominate, 58% passing a No. 200 mesh sieve. The weight of the soil was 120 lb per cu ft, with its water content, as removed from the fill. Engineers and textbooks expressed variant viewpoints as to the unit to be used in calculating the fill pressure. Some assumed that the water contained in the fill (the joints of the sheet-piling not being water-tight) counteracted the ocean hydrostatic pressure of 65 lb per cu ft, using the difference of 56 lb per cu ft as the effective unit loading produced by the fill. This would be an acceptable assumption provided the soil particles were spherical or granular, when the interstices or voids would, of course, be interconnected; but with the lamina-shaped particles coming to rest in still water with their flat sides horizontal, the structuralization of the resulting soil-fill entraps the water in the voids which probably can not be interconnected, such water being an integral part of the fill, and the laboratory weight of 120 lb is that which should be used. Thus, the safety of important structures is sometimes dependent on the weighing of all the physical characteristics of the soil particles, the usual considerations of mechanical analysis and the percentage of voids being insufficient if taken without thought of the structuralization of the particles.

MODEL LAW FOR MOTION OF SALT WATER THROUGH FRESH

By Morrough P. O'Brien[1] and John Cherno,[2]
Associate Members Am. Soc. C. E.

With Discussion by Messrs. W. E. Howland, Herbert D. Vogel, C. E. Grunsky, John B. Drisko, G. H. Keulegan, and Morrough P. O'Brien and John Cherno.

Synopsis

In connection with the investigations of the proposed "Salt-Water Barrier" in San Francisco Bay by the United States Engineer Department, certain questions were raised as to the action of salt water when flowing through fresh water. This problem was studied by means of hydraulic models, in the use of which the dimensional relations between model and prototype for similar flow were of primary importance.

Investigation showed that a model, geometrically similar to its prototype, could not be used for a study of the relative movement of salt water and fresh water, but that it must be distorted so that the scales for vertical dimensions, horizontal dimensions, and salinity satisfy a definite relation, which is expressed by Equations (14) of the paper.

Introduction

In connection with an investigation of the "salt-water barrier," that has been proposed as a means of keeping sea water from advancing into the delta of the Sacramento and San Joaquin Rivers, in California, certain problems arose regarding the motion of salt water when placed in contact with fresh water. All the sites proposed for the barrier would require locks for vessels of deep draft operating under an average difference in elevation in favor of fresh water of about 3 ft., with a depth over the sill of 40 ft. for the larger locks. At the Dillon Point site, there would be an adverse salt-water head

[2] Sacramento, Calif.

during part of the higher tides. These conditions made it possible for large volumes of salt water to pass through the locks into the fresh-water pool with each inbound lockage and thus defeat the purpose of the barrier. As the available data were scanty and indefinite, and to some extent conflicting, it was decided to study the problem through the use of hydraulic models, and, as the first step, a series of experiments were made in the Hydraulic Laboratory of the University of California to determine the model law governing the motion of salt water through fresh water. Although considerable information was obtained regarding dilution and methods of flushing salt water out of fresh-water reservoirs, this paper is concerned only with the derivation and experimental confirmation of the model law governing the dynamical aspects of the problem.

NOTATION

The notation used in this paper is adapted to the suggestions of the Society's Special Committee on Irrigation Hydraulics.[8] Symbols that are used only in derivations and do not appear in the final formulas, will be introduced at their proper place and are omitted from the following list:

b = scale ratio.
d = depth of water, in feet; d_h = gate opening.
d' = depth in model; $b_d = \frac{d'}{d}$ = scale ratio for vertical dimensions.
g = acceleration of gravity.
l = width of lock.
$s = G_1 - G_2$ = salinity.
s' = salinity in model; $b_s = \frac{s'}{s}$ = scale ratio for salinity.
t = time, in seconds.
w = 62.5 lb. per cu. ft. = unit weight of water.
A = total area covered by salt water at any time, measured in terms of $V_0 \, l$.
G = specific gravity; G_1, of heavy liquid; G_2, of light liquid.
K = model characteristic $= \frac{L_0}{d^{2.5}\, s^{0.5}}$.
L = longitudinal distance along the channel; L_0 = length of lock.
L' = length in model; $b_L = \frac{L'}{L}$ = scale ratio for horizontal dimensions.
V = velocity of salt-water wave front, in feet per second; V_0 = initial velocity of salt-water wave front, in feet per second.
ν = kinetic viscosity as defined on page 585.

DESCRIPTION OF PHENOMENON

Before developing the theory or discussing the experimental results, a brief description of the phenomenon observed will be useful in defining the problem. The channel shown in Fig. 1 was arranged so that a vertical gate divided it into two compartments. The smaller compartment was filled with colored salt water while the remainder of the channel was filled with fresh water.

---

[8] *Proceedings*, Am. Soc. C. E., May 1932, p. 729.

The water surfaces on the two sides of the gate were brought to the same elevation, and the gate was then removed suddenly. The heavier salt water slid under the fresh water and moved along the bottom of the channel with a peculiar tumbling motion while the fresh water moved in the opposite direction along the surface.

The condition immediately after the gate was removed is shown in Fig. 2, the white streak in the middle of the photograph marking the original position of the gate. Fig. 3 shows the advancing wave front, which for sea water (specific gravity = 1.026), with a depth of 1.2 ft., had a velocity of approximately 0.50 ft. per sec. At some instant subsequent to the removal of the gate, the fresh water, moving into the smaller chamber, reached the rear wall, and the salt water continued to move along the channel as a slug of constantly diminishing height and increasing length. The initial height of the salt-water wave was almost exactly one-half the total depth as appears in Fig. 2. In Fig. 3, showing the wave at eight lock lengths from the initial position, the height has decreased to four-tenths of the depth. In Fig. 4, the advancing wave has piled up against the end of the channel and a reflected wave is about to start back along the surface of separation of the two liquids. Fig. 5 is a view of an experimental channel at Turlock, Calif., discussed subsequently.

THEORY

Consider a channel of rectangular cross-section and horizontal bottom, divided into two compartments containing liquids of different specific gravities. It is evident that, when the two liquid surfaces are at the same elevation, the forces on the two sides of the partition are not equal and that a relative motion of the two liquids will result when the partition is removed. Referring to Fig. 6, the line, *A O B,* represents the surface of separation of the two liquids at some time subsequent to an instantaneous removal of the gate. The heavier liquid is moving along the bottom, displacing a part of the lighter liquid, which is moving in the opposite direction along the surface.

Observation shows no motion of the salt water to the left of Section *C-C* and of the fresh water to the right of Section *E-E,* but all parts of both liquids acquire their full velocities, when they are reached by the planes, *C-C* and *E-E,* in such a short time that, for all practical purposes, infinite acceleration can be assumed. It was further observed that the point, *O,* is at one-half the depth and that no change in surface elevation occurs, so that the quantities of fresh water and salt water passing the gate section are equal and move with equal velocity, $V_0 = \frac{dx}{dt}$. The unbalanced force acting toward the right on the mass, $M = 2\,x\,\frac{d}{2}\,G_1\,\frac{w}{g} + 2\,x\,\frac{d}{2}\,G_2\,\frac{w}{g}$, of water between Sections *C-C* and *E-E* is;

$$w\,G_1\,\frac{d^2}{2} - w\,G_2\,\frac{d^2}{2} = w\,s\,\frac{d^2}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and is equal to the change of the momentum, $M\,V_0$, per second. Therefore,

$$w\,s\,\frac{d^2}{2} = \frac{d}{dt}\,(M\,V_0) = \frac{w}{g}\,d\,(G_1 + G_2)\,\frac{d}{dt}\left(x\,\frac{dx}{dt}\right) \quad \ldots\ldots\ldots (2)$$

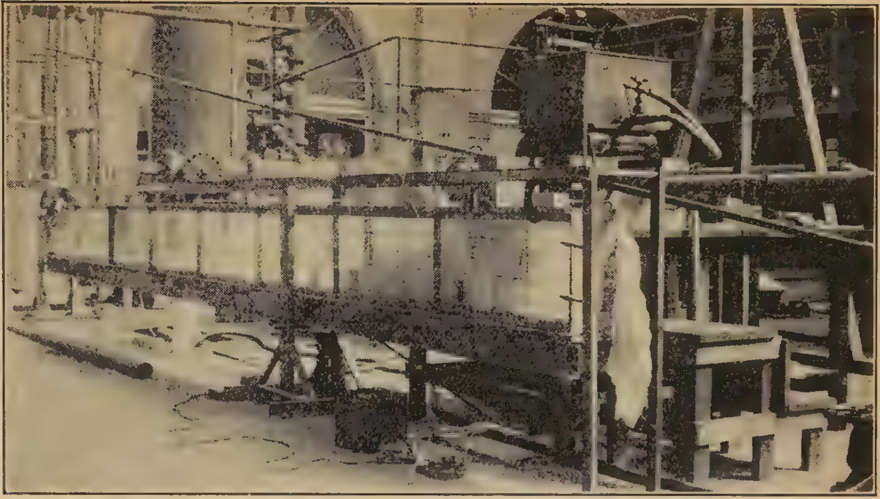

FIG. 1.—VIEW OF EXPERIMENTAL CHANNEL WITH GLASS SIDES.

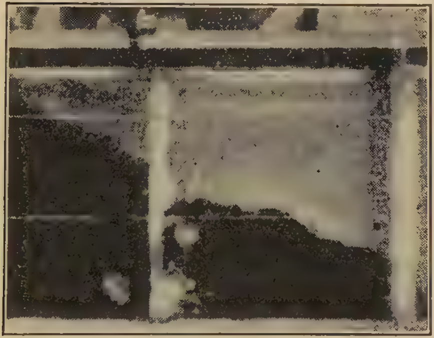

FIG. 2.—SALT WAVE LEAVING LOCK.

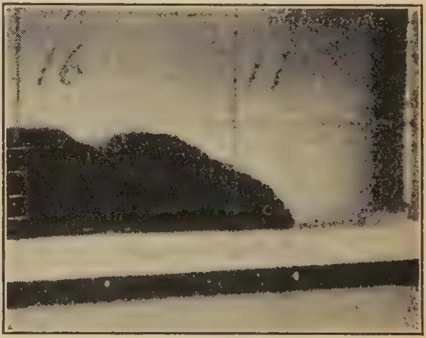

FIG. 3.—SALT WAVE AT ABOUT EIGHT LOCK LENGTHS FROM GATE.

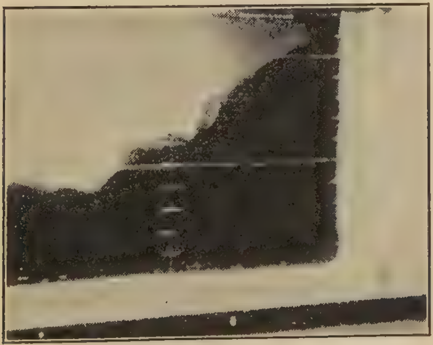

FIG. 4.—SALT WAVE STRIKING BULKHEAD END OF CHANNEL.

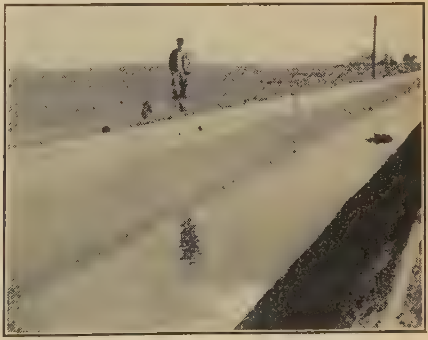

FIG. 5.—EXPERIMENTAL CHANNEL AT TURLOCK, CALIF.

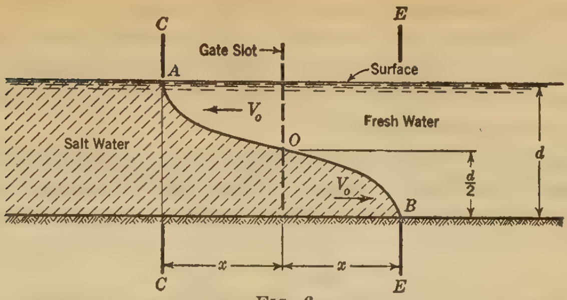

FIG. 6.

The first integral, considering that $x = 0$ for the moment, $t = 0$, when the gate is removed, is,

$$s\,\frac{d}{2}\,t = \frac{G_1 + G_2}{g}\,x\,\frac{dx}{dt} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The second integral is, therefore,

$$x = \pm\, t\sqrt{\frac{g\,d\,s}{2\,(G_1 + G_2)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Therefore,

$$V_0 = \frac{dx}{dt} = \pm\sqrt{\frac{g\,d\,s}{2\,(G_1 + G_2)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Since V_0 is independent of x and t, it follows that all salt water and fresh water is brought instantly to an initial velocity, V_0, until either Section *C-C* or Section *E-E* reaches the end of the testing flume. After that the foregoing assumed conditions no longer exist, and the subsequent advance of the salt water takes place, as shown in Fig. 7.

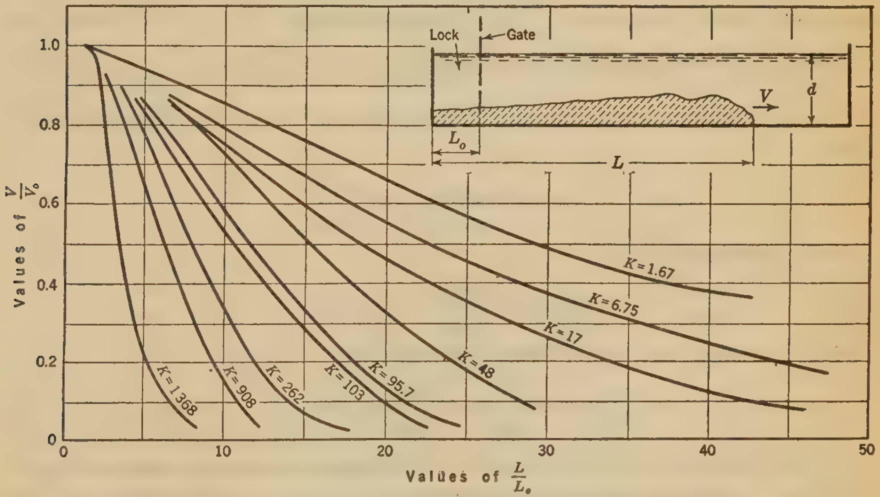

FIG. 7.—RELATION BETWEEN RATE OF DECREASE OF VELOCITY AND MODEL CHARACTERISTIC, *K* (LABORATORY EXPERIMENTS).

Tests might be expected to show initial velocities slightly less than V_0 as computed by Equation (5) because no friction losses have been taken into account. However, it will be shown presently that delays in opening the gate will cause initial velocities larger than V_0, so that no prediction of a systematic deviation can be made.

Another method of obtaining Equation (5) is to consider the potential energy converted into kinetic energy during the downward motion of the heavier liquid. If, in Fig. 8, d_g is the vertical distance from the sill of the gate to the center of gravity of a volume of liquid, B, which ultimately passes through the gate, the velocity of efflux can be obtained on the assumption that a counter flow of the lighter liquid occurs with the surface of separation at $\frac{d_h}{2}$, and with a velocity equal to the outflow velocity of the salt water. This is equivalent to assuming that the surfaces on the two sides of the gate remain at the same elevation after the gate is opened, and is based on direct observation. The center of gravity of B falls through the distance, $d_g - \frac{d_h}{4}$, but an equal volume of the lighter liquid is raised through the same distance. The decrease in the potential energy of the system is, then,

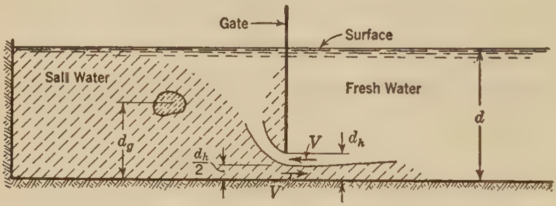

FIG. 8.

$$E_d = B\,w\,s\left(d_g - \frac{d_h}{4}\right)$$

The kinetic energy is,

$$E_K = \frac{B\,w\,V_1^2}{2\,g}\,(G_1 + G_2)$$

and, if the slight frictional losses are neglected,

$$\left(d_g - \frac{d_h}{4}\right)s = \frac{V_1^2}{2\,g}\,(G_1 + G_2) \;\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

If the lock is filled with salt water and the gate is opened a small distance, the initial velocity is obtained by making $d_g = d$ and $d_h = 0$, since the first fresh-water particles passing through the gate rise from the bottom to the surface. The initial velocity of efflux is, then,

$$V_1 = \sqrt{\frac{2\,g\,d\,s}{G_1 + G_2}} = 2\,V_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Equation (7) reduces to the ordinary orifice equation when $G_2 = 0$, corresponding to the discharge of water into air. If the gate is removed, $d_g = \frac{d}{2}$, $d_h = d$, and V_1 becomes equal to V_0 as obtained from Equation (5) for the same conditions (that is, removal of the gate).

Since a finite time is required for raising the gate, it follows that the observed initial velocity will lie between the value given by Equations (5) and (7), approaching the former value the more closely, the shorter the time of opening.

Referring to Fig. 6, the surface particles of the lighter liquid are moving toward the left and the question arises as to whether their velocity is created by a drop, $\frac{V_0^2}{2g}$, of the surface above Point B, as Bernoulli's theorem would require for steady flow. For $G_d = 0.025$ and $d = 1$, the drop, $\frac{V_0^2}{2g}$, would be about 0.003 ft. and, therefore, visible. The only surface disturbances observed, however, were those directly attributable to the opening of the gate and these were much smaller than the aforementioned amount.

As the total volume of liquid in the testing flume is constant, a drop of the surface at any place would have to be made up by a rise of the surface at some other place; that is, water would have to be lifted from below the original surface to above it, and, therefore, no drop of the surface could furnish the energy required to set water in motion. On the contrary, it would diminish the kinetic energy. Although it is not the intention to investigate herein the mechanism by which the different parts of the two liquids are set in motion, it can be stated that vertical displacements of the surface are not only unnecessary for the creation of the observed movements, but are opposed to them. It follows from the derivation of Equation (6) that such displacements would be reflected in a deficiency of V_0 and as shown subsequently, if such a deficiency exists at all, it is negligible.

THE MODEL LAW

The term, "model," refers to any hydraulic system by means of which the behavior of another system called the prototype, can be predicted, and the term, "model law," refers to the method of such prediction. The model law is a set of rules which assigns to each point of the prototype a corresponding point in the model and assigns the relations existing between the physical properties at corresponding points.

In the usual case, the required point-to-point relationship between the model and its prototype is obtained by making them geometrically similar at least to the extent of using only one scale ratio for horizontal dimensions and one for vertical dimensions. When these scale ratios are equal, the model and prototype are geometrically similar in the ordinary sense; otherwise, the model is "distorted." Another requirement is that the ratio of the measured quantities at pairs of corresponding points shall be the same for all points. For example, if the velocity in the model is one-half the velocity in the prototype at any pair of corresponding points, the velocity at any point in the model should be one-half the velocity at the corresponding point in the prototype. In other words, the scale ratio of velocities is to be a constant and a similar relation should hold true of all other measured quantities.

Whether it is possible to build models that represent their prototypes in every detail will not be discussed here. In practice, models are always used for the study of a limited number of phenomena and should be built so that these phenomena are represented properly. Minor associated phenomena must often be represented incompletely or even incorrectly and the success of a model experiment depends upon whether these neglected phenomena are controlling factors.

The present problem is the derivation of the model law governing the intrusion of salt water into fresh water in a shallow basin such as San Francisco Bay. The ultimate problem is a study of the distance traversed by the salt water, the dilution it undergoes during the motion, and its velocity at points along its path. It is known from direct observation that the vertical motion involved can be neglected because it is small as compared with the horizontal motion and because it occurs in a time that is short as compared with the time required for the entire process, and the model law will be based upon these assumptions.

Transference of the data from the model to the prototype will require the six ratios: Horizontal dimensions; vertical dimensions; velocities; time; salinity; and dilution. The dilution itself is a ratio and has no dimensions and, consequently, its value should be the same in model and prototype at corresponding points. The first five scale ratios are not independent and it is necessary to determine the relation between them.

In the prototype, the velocity is, $V = \dfrac{dx}{dt}$, and the corresponding quantity in the model is, $V' = \dfrac{dx'}{dt'} = \dfrac{b_L}{b_t}\dfrac{dx}{dt} = \dfrac{b_L}{b_t} V$. The velocity ratio is, therefore,

$$\frac{V'}{V} = b_v = \frac{b_L}{b_t} \quad \text{..........................(8)}$$

From Equation (5), the initial velocities are,

$$V_0 = \sqrt{ds}\,\sqrt{\frac{g}{2\,(G_1 + G_2)}}$$

in the prototype, and,

$$V'_0 = \sqrt{d'\,s'}\,\sqrt{\frac{g}{2\,(G'_1 + G'_2)}}$$

in the model. Therefore,

$$\left(\frac{V'_0}{V_0}\right)^2 = \frac{d'}{d} \times \frac{s'}{s} \times \frac{G_1 + G_2}{G'_1 + G'_2}$$

or,

$$b^2_v = b_d\,b_s\,b^{-1}_{(G_1 + G_2)} \quad \text{..........................(9)}$$

If salt water and fresh water are to be used in the model, $G_2 = 1.00$, and G_1 ranges from 1.00 to 1.20, so that $b_{(G_1 + G_2)}$ ranges from about 0.9 to 1.1 and ordinarily will be close to 1.0. For simplicity this ratio will be assumed equal to 1.00 in the following discussion unless otherwise specified. On this basis, Equation (9) becomes,

$$b^2_v = b_d \, b_s \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

A third relation between the scale ratios is found in the general equations of internal friction, which have the form,

$$\frac{w}{g}\frac{dV}{dt} + \frac{dp}{dx} - \mu \left\{ \frac{d^2V}{dx^2} + \frac{d^2V}{dy^2} + \frac{d^2V}{dz^2} \right\} = 0$$

for the X-direction, which is horizontal. The first term represents the inertia of a particle; the second, the unbalanced force acting on it in the X-direction; and, the third, the internal friction. Here, μ is a coefficient of internal friction which is ordinarily the coefficient of absolute viscosity. In the present case, μ may differ from the viscosity of either of the liquids in contact. The absolute viscosity divided by the density, $\frac{w}{g}$, is usually referred to as the kinematic viscosity and will be represented by ν. It will be assumed to have the same value for both model and prototype unless otherwise specified.

A similar equation can be written for the Y-direction which is also horizontal. The Z-direction is not considered since vertical motions are neglected.

Let P denote a hydraulic force. Fig. 9 shows that $\frac{dp}{dx}$ may be written as $\frac{d\,(w\,H\,s)}{dx}$ because of the horizontal water surface. Direct observation shows that salt water tends to move along the bottom of a channel as a coherent slug and that fresh water moves over the top of it at about the same velocity in the opposite direction. The velocity gradient, therefore, is large at the surface of separation and relatively small in all other directions and at all other positions. In other words, practically all the work of internal friction is done in the transition layer.

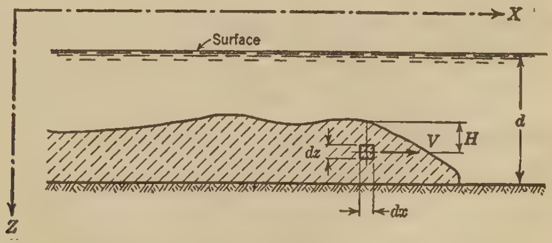

FIG. 9.

In view of the foregoing considerations, the equation of motion is simplified to,

$$\frac{dV}{dt} + g\,\frac{d\,(H\,s)}{dx} - \nu\,\frac{d^2 V}{d\,z^2} = 0 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

after dividing through by $\frac{w}{g}$. Writing the corresponding equation for the model and remembering that H is a vertical dimension,

$$\frac{d\,V'}{dt'} + g\,\frac{d\,(H'\,s')}{dx'} - \nu\,\frac{d^2\,V'}{d\,z'^{\,2}} = \frac{b_v}{b_t}\,\frac{d\,V}{dt} + \frac{b_d\,b_s}{b_L}\,\frac{d\,(H\,s)}{dx} - \frac{b_v}{b^2_d}\,\nu\,\frac{d^2\,V}{dz^2} = 0 \;..(12)$$

Equations (11) and (12) can be equal only if,

$$\frac{b_v}{b_t} = \frac{b_d\;b_s}{b_L} = \frac{b_v}{b^2_d} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

The physical meaning of Equation (13) is that the inertia, pressure, and friction forces in the prototype must be reduced in the same ratio in the model.

Equations (8), (10), and (13) are to be satisfied simultaneously. Taking b_d and b_s as the independent variables, these equations give as the model relations:

$$b_L = b_d^{2.5}\,b_s^{0.5} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14a)$$

$$b_v = b_d^{0.5}\,b_s^{0.5} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14b)$$

$$b_t = b_d^2 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14c)$$

The ratios, b_s and b_d, have been chosen as the independent variables because they are easiest to control in practice. Equation (14*a*) is of primary importance in the construction of a model. Replacing the ratios by characteristic dimensions such as the length of a lock, L_0, the depth, d, and the initial salinity, s, Equation (14*a*) gives,

$$\frac{b_L}{b_d^{2.5}\,b_s^{0.5}} = 1 = \frac{L'_0}{L_0}\left(\frac{s}{s'}\right)^{0.5}\left(\frac{d}{d'}\right)^{2.5}$$

Separating the quantities for model and prototype,

$$\frac{L'_0}{d'^{\,2.5}\,s'^{\,0.5}} = \frac{L_0}{d^{2.5}\,s^{0.5}} = K \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which, K is the simplified criterion of similarity.

Retaining both g and ν as variables, the complete model law is,

$$\frac{L_0\,\nu}{g^{0.5}\,s^{0.5}\,d^{2.5}} = K' \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

which is dimensionless. Equation (15) is applicable to the case of salt water and fresh water because ν is approximately constant, but Equation (16) may be necessary if liquids are used in the model entirely different from those in the prototype. The ratio, $b_{(G_1+G_2)}$, might also have to be included in this case.

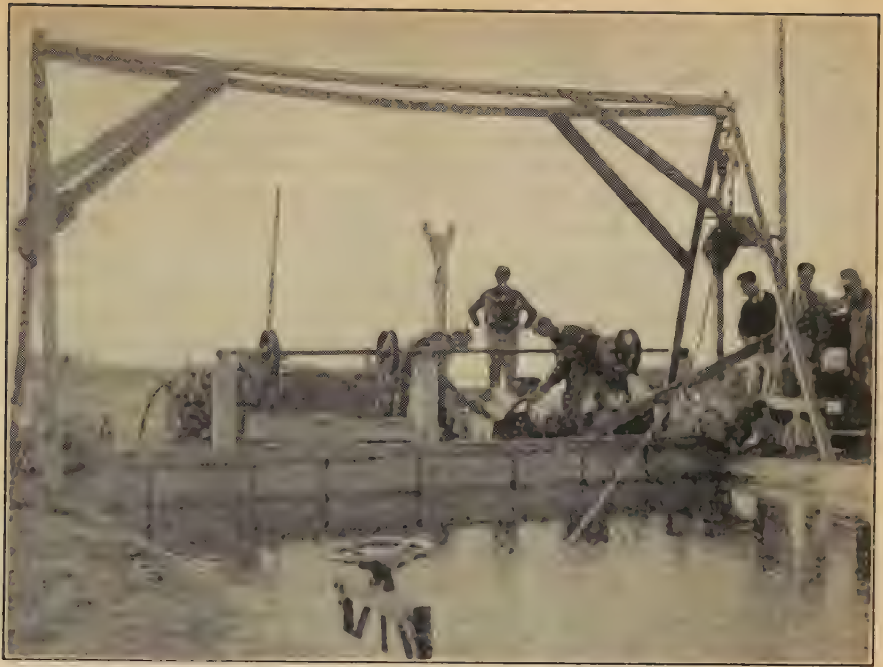

FIG. 10.—TURLOCK EXPERIMENTS: GATE LOWERED FOR START OF EXPERIMENT

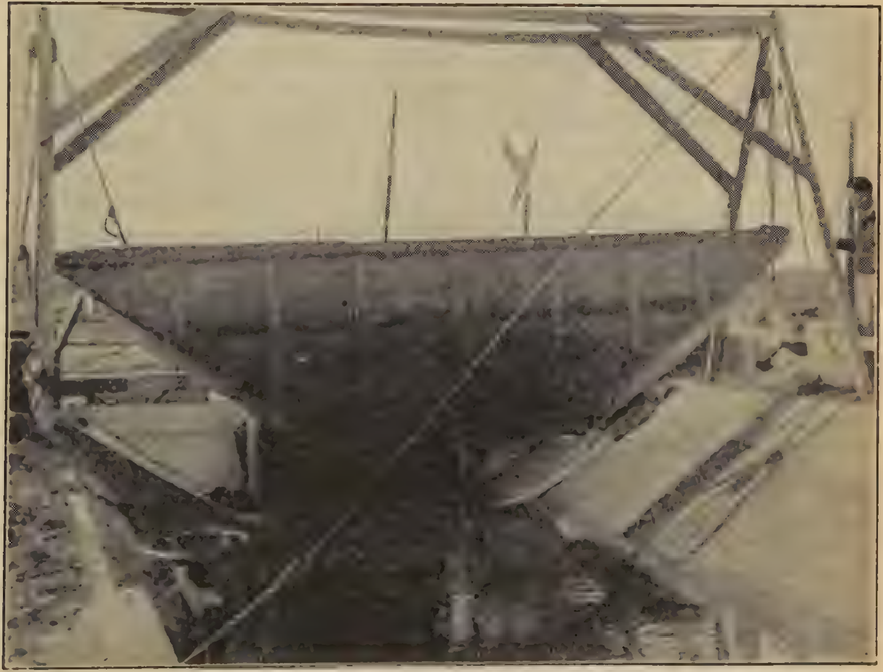

FIG. 11.—TURLOCK EXPERIMENTS: GATE RAISED.

EXPERIMENTAL PROCEDURE

The glass-sided channel (Fig. 1) used in the first series of experiments, was 24.4 ft. long, 0.5 ft. wide, and 1.25 ft. deep, placed so that the bottom was horizontal. A thin, sheet-metal gate, moving in vertical guides placed above the channel proper and sealed with rubber strips, coated with grease, was used instead of a lock-gate. The volume displaced by the gate was insignificant, and the surface disturbances resulting from its removal were not sufficient to have an appreciable effect on the velocities. The specific gravities of the liquids were measured by a hydrometer or a specific gravity balance, and time intervals by a chronograph and stop-watches. A co-ordinate system in feet and tenths was drawn on the glass plates with a grease pencil.

The liquid used to fill the lock was a solution of crude granulated rock salt in water, colored to a deep red with potassium permanganate. As the gate was unable to withstand any considerable side thrust, the channel was first filled to the desired depth with fresh water, and the gate was then put in position and sealed with cup grease. The fresh water was siphoned from the surface of the lock chamber as the saline solution was discharged at the bottom, and the two water surfaces were brought to the same elevation by point-gauges reading to 0.001 ft. The lock chamber was then thoroughly stirred by bubbling before the specific gravity was measured. The behavior of the salt water following the removal of the gate has been described previously.

Following the laboratory experiments, a few additional tests were made in a concrete-lined irrigation canal of trapezoidal section at Turlock, Calif. (See Fig. 5.) This channel had a bottom width of 6 ft., side slopes of 1 on $1\frac{1}{2}$, a maximum depth of 4 ft., a bottom slope of 1 on 2 000, and a length of 2 600 ft. The gate, which consisted of a trapezoidal wooden frame covered with oil-cloth, was placed at the lower end of the experimental section so that the advancing wave traveled up along the bottom of the channel. The manner of conducting the tests was similar to that in the laboratory, but the probable error was much greater. In addition, a current along the channel, due to leakage past the gates, was noticeable in some experiments. During certain experiments, wind-driven surface currents created counter currents on the bottom opposing the progress of the salt solution. The gate was lifted by block and tackle and the time required to lift it clear of the water surface was relatively greater than in the laboratory, a condition which, according to Equation (7), would result in a relatively higher initial velocity. The channel and gate used at Turlock appear in Figs. 10 and 11.

AGREEMENT BETWEEN THEORY AND EXPERIMENT

In Table 1, the measured initial velocities in the laboratory experiments are compared with the velocities computed from Equation (5). The data were picked so as to give as a wide range of d, s, and L_0 as possible and to include tests giving the maximum deviation from the formula. The differences between the experimental results and the equation are erratic and do not indicate any general tendency for the actual velocity to be greater or less than that given by the formula. Considering the data of Table 1, it can be stated that Equation (5) represents the initial velocity in a rectangular channel with a probable error of 2 per cent.

TABLE 1.—INITIAL VELOCITIES MEASURED IN LABORATORY

Test No.	d, in feet	L_0, in feet	s	V_0, in feet per second (computed)	V_0, in feet per second (observed)	Percentage, deviation
A-2......	1.20	1.79	0.029	0.528	0.595	+11.2
A-5.......	0.80	1.79	0.030	0.437	0.416	—4.8
A-6......	0.40	1.79	0.032	0.319	0.298	—6.3
A-25.....	0.415	0.90	0.0302	0.316	0.297	—6.0
A-23.....	0.412	0.32	0.0319	0.324	0.298	—8.0
A-14......	1.20	8.95	0.032	0.554	0.532	—4.0
A-10.....	1.20	0.39	0.023	0.470	0.436	—7.1
A-4......	1.20	1.79	0.015	0.380	0.379	—0.2
A-12......	1.19	1.79	0.063	0.767	0.912	+18.9
A-13......	1.20	1.79	0.101	0.970	0.995	+ 2.6

Table 2 shows the initial velocities measured in the irrigation channel at Turlock. As would be expected from the time required to open the gate, the observed velocities are in excess of the computed values, and the percentage deviation increases with the depth. Segregating the tests according to the depth, the average deviations for depths of 2, 3, and 4 ft. are found to be 4.0%, 12.6%, and 19.6%, respectively.

SPREADING EXPERIMENTS

An additional check on the model law was made in a sheet-metal tank of irregular shape, approximately 25 ft. long, 6 ft. wide, and 1 ft. deep. The method of conducting the experiments was entirely similar to that in the glass channel with the difference that the bottom was covered with a thin layer of sand, on which a co-ordinate system of white lines was drawn with plaster of Paris. A lock, 1.04 ft. long and 0.82 ft. wide, with wing-walls, forming a continuation of the sides of the lock and projecting 0.4 ft., was placed at the side of the tank for part of the tests and at the end for the remainder. This arrangement permitted lateral motion of the salt solution which had not been considered in any of the previous experiments. In deriving Equation (12) only the forces in the *X*-direction were considered; a similar line of reasoning applied in the Y-direction would yield the same result, and, consequently, the same model characteristic, K, should completely describe the motion in all systems having horizontal dimensions proportional to L_0 and depth proportional to d.

The results of these experiments on the effect of the spreading are shown in Fig. 12, for the lock at the end of the tank (Fig. 12(*a*)), and the side, (Fig. 12(*b*)), respectively. The symbols used have the following significance:

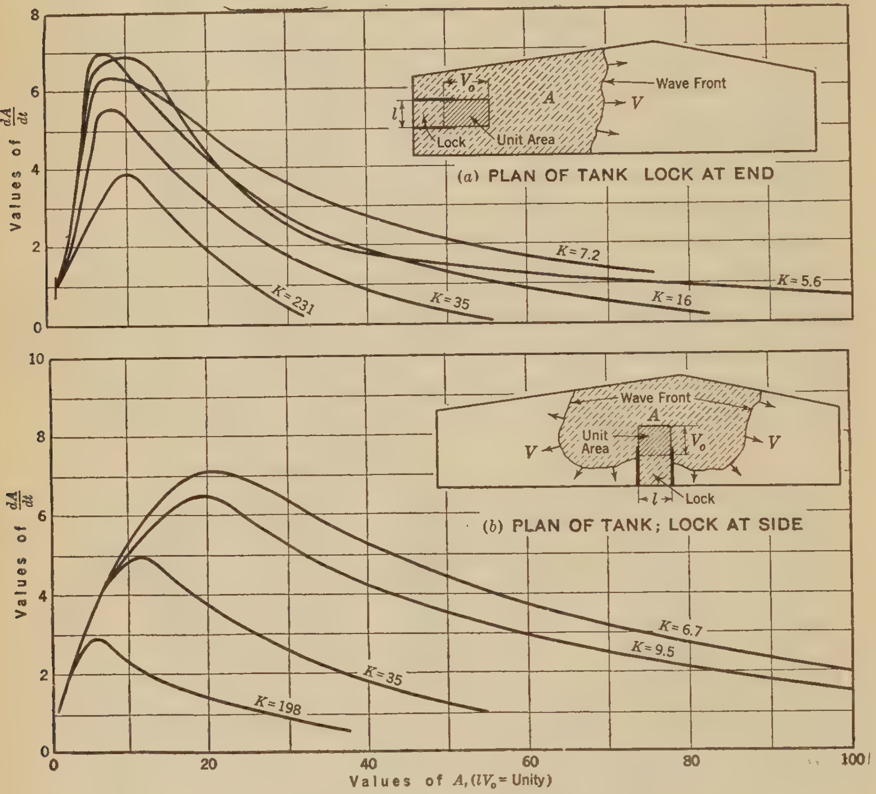

FIG. 12.—RATE OF SPREADING SALT WATER OVER A HORIZONTAL PLANE.

$$V_0 = \sqrt{\frac{gd}{2}}\sqrt{\frac{s}{G_1 + G_2}} = \text{the initial velocity of the salt water.}$$

l = the width of the lock.

A = the total area covered by salt water at any time, measured in terms of $l\,V_0$.

$\frac{dA}{dt}$ = the time rate of increase of A.

As explained previously, the bottom of the channel was covered with a co-ordinate system of white lines, and as the wave spread out from the lock in all directions, the time at which the wave front reached various points in that system was noted. Contours representing the area covered at any time were then drawn and, by measuring the areas inside these lines, the values of A and $\frac{dA}{dt}$ were obtained.

In the initial stage of the motion, the velocity is relatively great and the time is difficult to measure precisely, so that the experimental points show considerable scattering in this region; but as the velocity decreases, the points fall more regularly. All the curves exhibit the same general shape and, with only one exception, they arrange themselves according to the value of K. The length of the lock was constant for all these experiments, but the depth ranged from 0.18 to 0.8 ft. and the specific gravity of the salt solution ranged from 1.046 to 1.098.

The model law derived previously indicated that when the value of $\frac{L_0}{d^{2.5}\ s^{0.5}}$ is the same for two structures having horizontal dimensions proportional to L_0 and vertical dimensions proportional to d, the entire motion of the salt water should be similar. A few of the tests made in the glass channel are shown in Fig. 7. The ordinates represent the velocity in percentage of the initial velocity of advance. The abscissas represent the number of lock lengths from the closed end of the lock to the point at which the velocity was measured. It is to be noted particularly that all the curves have the same general shape and that they distribute themselves according to the value of K. Twenty-three curves similar to those in Fig. 7 were used to obtain Fig. 13, which shows the relation between the number of lock lengths from the closed end of the lock, at which the velocity is reduced to a certain percentage of the initial velocity, and K, the model characteristic.

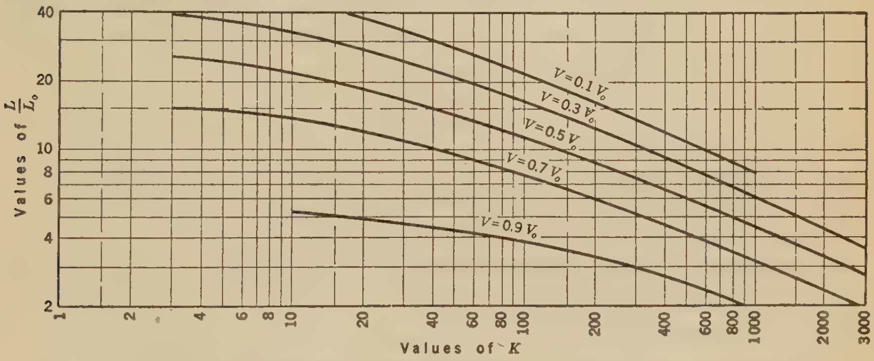

FIG. 13.—RELATION BETWEEN RATE OF DECREASE AND MODEL CHARACTERISTIC, K.

The curves of Fig. 13 permit drawing the velocity curve for any value of K. The actual velocity in any particular case may be obtained by multiplying each ordinate by the initial velocity given by Equation (5).

Fig. 14 shows the velocity curves obtained at Turlock. As mentioned previously, the initial velocity in most cases is high, but the curves for all twelve tests arranged themselves according to the value of K. Only six of the curves are shown on the graph, in order to avoid confusion, but the remainder showed equal regularity both in shape and location.

In Fig. 14, curves (dotted) drawn from the data in Fig. 13 are compared with the actual data obtained at Turlock for equal values of *K*, the model characteristic. The initial velocity at Turlock was greater than that observed in the laboratory, but the velocity diminished more rapidly, due principally to the upward slope of the bottom. Other contributing factors in the more rapid decrease in velocity at Turlock were the currents of fresh-water leakage through the upper bulkhead, and the wind. Allowing for all sources of error in these large-scale tests and for the fact that the trapezoidal channel is not quite equivalent to the rectangular channel used in the laboratory, the writers consider the results of the Turlock tests to be a satisfactory confirmation of the results obtained in the laboratory.

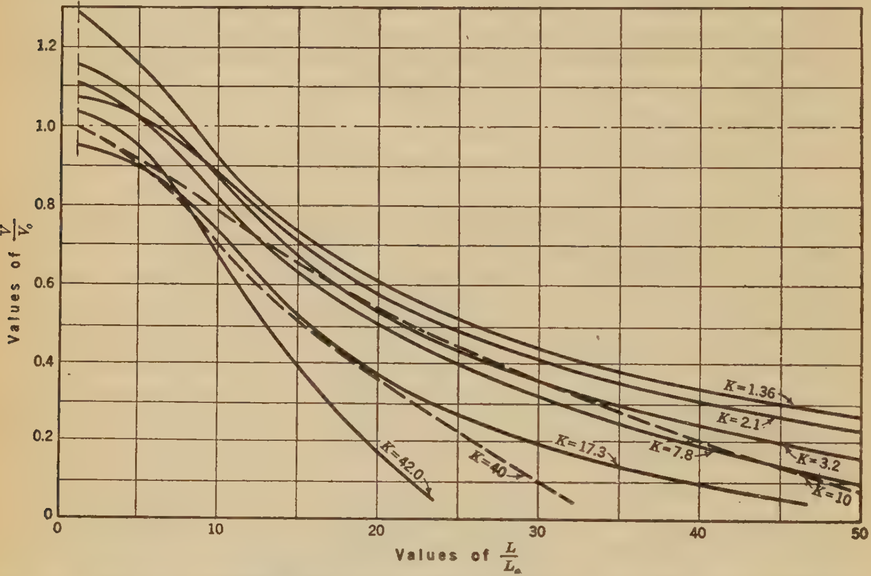

FIG. 14.—RELATION BETWEEN RATE OF DECREASE OF VELOCITY AND MODEL CHARACTERISTIC, *K*; TURLOCK EXPERIMENTS.

CONCLUSIONS

From an assumed character of the forces involved in the motion of salt water through fresh water, the model law governing the similarity was determined to be $\frac{L_0}{d^{2.5}\ s^{0.5}} = \text{constant} = K$, in which, L_0 is any characteristic horizontal dimension, *d* is a characteristic vertical dimension, and *s* is a characteristic salinity.

The experimental results show that, regardless of the absolute values involved, the velocity curves distribute themselves according to the values of *K*, and for two tests having values of *K* that are approximately equal, the curves lie very nearly parallel throughout their length. From this, it may be concluded that, if the difference in the values of K for two tests is zero, the velocity curves will coincide, and, consequently, K is the criterion for dynamical similarity.

Furthermore, since the model law, as derived theoretically, coincides with that found experimentally, the fundamental assumption made in the derivation of the law — that is, the assumption that the internal friction acts like a force equal to $\nu \frac{d^2 V}{dZ^2} dx\, dy\, dz$ — is essentially correct and no forces other than the two considered in deriving the model law are of major importance.

One other force to which attention was paid is the friction at the bottom of the testing flume. Most of the tests were run on a hardwood bottom painted with red lead. Similar tests were run with the bottom covered with coarse sand for comparison, but no difference in the velocity of the salt water was found. Since the fresh water moves in a direction opposite to that of the salt water in the upper part of the flume, the vertical velocity gradient is exceedingly large at the surface of separation of the two liquids, and it is natural that the friction developed in these transition layers should be great enough to govern the motion almost completely.

It is to be emphasized that Equation (15) is valid only for cases in which the principal motion is horizontal. It is also restricted to experiments in which the kinematic viscosity is the same in both model and prototype; otherwise, Equation (16) is to be used. Another restriction is that the velocities and depths in the model must not produce laminar flow, if turbulent flow exists in the prototype.

The present experiments do not indicate any quantitative limitations of the validity of Equation (15). However, the writers are of the opinion that an actual lock having a length twenty to thirty times its depth could be studied in a model having a length only one-half, or even one-third, of the depth using salt water in the model, but they do not feel that the present experiments alone justify the use of such a combination as ether and mercury to represent the fresh and salt water, respectively. Further experimental work should be done before such a drastic step is taken.

As an illustration of the application of these conclusions, assume that model tests are to be made concerning the distribution and dilution of salt water flowing from the Ballard Locks into the Lake Washington Ship Canal at Seattle, Wash., and compute the dimensions to be used in the construction of a model according to the model law derived in this paper. The actual dimensions are: Length of canal from locks to Lake Washington, 33 000 ft.; depth, length, and width of the locks, 37, 825, and 80 ft. respectively. The law gives a relation between three scale ratios, namely, a ratio for vertical dimensions, b_d; one for horizontal dimensions, b_L; and one for salinity, b_s. Two of the scale ratios can be chosen arbitrarily and the third one is then determined by the relation,

$$\frac{b_L}{b_d^{2.5}\ b_s^{0.5}} = 1 \qquad \text{.........................(17)}$$

Table 3 shows the dimensions assumed by the large lock, and by the distance from the locks to the entrance into Lake Washington in models of different scales. A set of vertical scales is chosen, and it is assumed that either the tests would be run with water of the same salinity as that of Puget Sound (which is about 0.02), giving a salinity ratio of unity, or with water of a salinity of 0.2 which is about as high as could be made, and in which case the salinity ratio would be 10:1. The horizontal scales as computed from the model law and the resulting dimensions of the large lock and the distance to Lake Washington in the model, are also shown in Table 3.

ACKNOWLEDGMENTS

These studies were made by the United States Engineer Department, San Francisco District, in conjunction with the University of California. They formed a part of investigations made for a "Report on Proposed Salt Water Barrier, Sacramento, San Joaquin, and Kern Rivers, California," pursuant to the provisions of House Document No. 308, 69th Congress, First Session.

The investigations were made under the direction of E. H. Ropes, Maj., Corps of Engineers, U. S. A., Assoc. M. Am. Soc. C. E., District Engineer; C. A. Mees, M. Am. Soc. C. E., Principal Engineer, who was in charge of the work with H. G. Gerdes, Assoc. M. Am. Soc. C. E., Associate Engineer as Assistant. Most of the testing was done in the Hydraulic Laboratory of the University of California and the remainder in an irrigation ditch of the Turlock Irrigation District. The writers were in charge of the tests, Professor O'Brien for the University of California and Mr. Cherno for the U. S. Engineer Department.

DISCUSSION

W. E. Howland,[4] Assoc. M. Am. Soc. C. E. (by letter).—This study seems to be a novel and most promising application of the methods of model testing to a baffling and important problem. It would seem to suggest methods for the study of other related problems, such as the spread of sewage over the surface of a salt-water harbor already treated[5] by A. M. Rawn and H. K. Palmer, Members, Am. Soc. C. E., and others.

Referring to the authors' Fig. 6, and considering as a free body that portion of the fluid between a section taken a little to the left of Section *C-C*, and a section taken a little to the right of Section *E-E*, the horizontal forces acting on this free body would be $\frac{1}{2} s w d^2$, toward the right (if the levels are as shown) and also friction forces the resultant of which probably acts toward the left. Are these forces necessarily in equilibrium? Is it not possible that they have a resultant acting to the right that tends to move the entire body in that direction, tending thus to depress the water surface at *C* and raise it at *E*? If this is not so, it is difficult to understand how the fresh water between *C* and *E* can start to move toward the left notwithstanding the authors' statement that the only surface disturbances observed were those directly attributable to the opening of the gate.

Does the interface of the salt and fresh water incline as shown in Fig. 6? If so, one can understand how the pressure gradient in the salt water might be toward the right, imparting motion in that direction. If, however, this interface slopes toward the left, as suggested in Fig. 7, it would seem necessary to assume a considerable decrease of momentum in the direction of motion. Possibly an assumption of mixing that would have the result of clouding the effects, could account for the appearance indicated. If the former assumption is correct, it would seem that the condition illustrated in Fig. 7 would be a secondary one and would not be the condition prevailing at the beginning of the motion. In order to make the salt water continue to move to the right, it would seem that there must be a pressure gradient predominating toward the right within the salt water. Fig. 7 illustrates a most interesting condition, in which all the exterior forces on the moving salt water are tending to slow it down. This might explain the rapid decrease in velocity observed in certain of the experiments.

If the writer's assumptions as to the depression of the water surface near *C* and the corresponding rise near *E*, are correct, it should be possible to detect a movement of the surface water toward *C* in both directions and away from *E* in both directions. Were any such movements detected? Furthermore, it might be supposed that such changes in elevation of surface would give rise to waves of small amplitude which, in time, would cause a jerky or intermittent motion of colored salt water. Was this effect noticed?

[5] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1036.

Messrs. Rawn and Palmer[6] recorded as an observation of their experiments that "colored fresh water moved over the salt water in concentric waves"; but, of course, the conditions in these two experiments are entirely different.

Similar considerations would suggest that when the gate is opened only a slight amount at the bottom, as indicated in Fig. 8, it is possible that the water would move entirely in one direction—that is, toward the fresh water—and that no fresh water would move in the other direction. Therefore, the initial velocity toward the fresh water might be even greater than as computed; that is, it might be nearly as great as $\sqrt{2\,g}\sqrt{\frac{d s}{G_1}}$. Have any direct observation of this case been made?

The writer has obtained the model law (Equation (16)) by methods which he believes to be similar to those used by the authors, by assuming that: (*a*) The impressed forces on a body between Sections *C-C* and *E-E* (Fig. 6) are proportional to $w\ s\ d^2$; (*b*) the resistant forces are proportional to $v d$, x, *or* L, and kinematic viscosity; and (*c*) the inertia forces are proportional to $\frac{w}{g}$, L, d, and $\frac{v^2}{L}$. With these assumptions he has written the equation which states that the ratio of these three pairs of corresponding forces must be the same in the model as in the prototype. The assumption of constant viscosity is also made.

When another pair of resisting forces is introduced, assuming that these forces vary indirectly with the velocity squared, v^2, the area of the stream, $d\,L$, and, inversely, as the hydraulic radius assumed to be proportional to d, another limitation is obtained which states that $L = d$; and then the model law becomes,

$$\frac{1}{d^{1.5}\ s^{0.5}} = \text{a constant} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

Thus, for the similarity of all these forces, a scale ratio of $\sqrt[3]{10}$ would be required when the salinity ratio is 10, which is too large to be of much practical value. Fortunately, the authors' experiments have clearly shown that for their problem this additional condition need not be met.

There is one other effect which, under certain conditions, might modify the model law and should receive further study before the law is given a wide application. This effect is mixing. Consider a particle in the fresh water moving over the top of the body of salt water. The impressed force in this case is proportional, not only to the surface gradient (which, in turn, is dependent upon the depth, d), but also upon the density gradient, because both affect the resultant pressure in the direction of motion. The density gradient, of course, is dependent upon mixing. If it can be shown that adherence to the model law will automatically give density gradients either negligible or proportional to the surface gradient, or if, in some other way, it can be shown that all the corresponding important forces are in proper ratio, then the objection just raised would have been overcome. The consistency of the experimental data presented does, in a measure, prove this for the case studied, but any information on the degree of mixing or of salinity that may have been obtained in these experiments, would be a most useful addition to the paper.

---

[6] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1047.

As an illustration of the possible effect of mixing upon the model law, let it be assumed that the resistance offered to the motion is dependent, not only upon the area of contact between the two moving fluids, L, the velocity gradient, $\frac{v}{L}$, and the viscosity, but also to some extent upon the differences in density between the two fluids, s. This is reasonable since it is known that the mixing is the greater, the less the difference of the density of the fluids; and, of course, the greater the mixing of the two oppositely moving fluids, the greater the resistance to their motion. The late Kenneth Allen, M. Am. Soc. C. E., has expressed[7] this idea in the statement: "It is clear that salinity of a body of water receiving sewage is an important factor in its diffusion." Let it be assumed that $\frac{1}{s^n}$ should be introduced into Equation (18). Then, it can be shown that the model law would be changed to,

$$\frac{d^{2.5}\ s^{(0.5\,+\,0.5n)}}{L} = \text{a constant}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19)$$

in which, n is an unknown, but positive, exponent.

In the case studied by Messrs. Rawn and Palmer, the mixing effect was a significant factor. Indeed, its evaluation was the object of their study, and they concluded that no stratification at all is possible if the dilution exceeds 1:200.

Does it not seem plausible that the more rapid decrease in velocity observed for large values of k (when both d and s are small) may have been occasioned by the greater mixing that takes place under those conditions? The effect of a small s upon mixing has just been considered. A small d would give rise to large velocity gradients which, in turn, would seem to promote mixing. Since the forces arising from turbulence have been neglected, in deriving the model law, it would seem that the necessity of providing turbulent conditions in both model and prototype would arise from the requirement of producing similar mixing effects. Surely, if the effect of mixing is important, then immiscible liquids, as mentioned under "Conclusions," could not be used in the model.

The validity of K as a criterion for the case studied would be more convincing if the authors would show the actual computed values for several points in Fig. 7, so that it would be possible to prove from actual data that for radically different values of s and d, with identical values of K, the points as plotted would be substantially coincident.

---

[7] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1065.

HERBERT D. VOGEL,[8] ASSOC. M. AM. SOC. C. E. (by letter).—The ideas presented by Professor O'Brien and Mr. Cherno are particularly refreshing at this time in that they serve so admirably to reflect the broader attitude toward design and the use of hydraulic models, that distinguishes the research work of American from European investigators. The writer has frequently urged abandoning the rigid limits of geometric similitude when dealing with models of rivers and other open channels, for the reason that similarity of effect is of infinitely greater importance than a mere similarity of shape. In practice, every model is distorted in some respects, and the investigator must be on guard continually to avoid overlooking the less obvious distortions of properties and forces while attempting to avoid geometric distortion, which in the last analysis can be held responsible for few important errors.

As the authors suggest, the first and most important step in designing the model is to choose a vertical scale that will result in the production of turbulent flow and properly measurable depths. Following this, consideration must be taken of the size of the prototype, the space available for the model, and the water supply at hand. From a practical standpoint these considerations must determine the horizontal scale, which will approximately equal the ratio of the length of available laboratory floor space to the length of the prototype. The distortion will be the ratio between the vertical and horizontal scales, and other scale values must then be determined to conform dynamically with the originally chosen ratios, keeping in mind continually the main purpose of the investigation.

In the case of experiments relative to the motion of salt water through fresh, the O'Brien–Cherno law is provided as a handy tool to determine the salinity ratio necessary for dynamic similarity when horizontal and vertical scales have been established. The law, of course, could be applied conversely to determine the horizontal scale of the model, having already decided upon the vertical scale and salinity ratio, but it is believed that its greatest utility will be in determining a salinity ratio after arbitrarily selecting the linear relationships. An interesting point is raised in conjecturing the practical limits to which the law may be applied, although there appears, offhand, no valid reason for avoiding what might appear to be extreme distortions. In the absence, however, of cogent reasons for resorting to gross geometric distortion and in the interest of conservatism it would seem best to distort no more than is necessary to insure turbulence and measurable depths. Practically every experimenter has laid down limits of distortion that, in his opinion, must not be exceeded, and it is of more than passing interest to note that the imposed limit in each case tends to vary directly with the size of prototype in which the particular experimenter is most interested. Since the writer has to deal largely with flood control and navigation problems relative to the Mississippi River and its tributaries, he is inclined to be rather generous in the matter.

In closing, it is desired to call attention to the notations and symbols used at the United States Waterways Experiment Station, suggesting that their general adoption in the United States might considerably simplify the reading and understanding of technical papers on the subject of similitude. As used by the U. S. Waterways Experiment Station: L_m = a horizontal length in the model; L_n = a corresponding length in Nature (prototype); $l = \frac{L_m}{L_n}$ = the horizontal linear scale; $d = \frac{D_m}{D_n}$ = the vertical linear or depth scale; $v = \frac{V_m}{V_n}$ = the velocity scale; etc. From the foregoing it is seen that capital letters with suitable subscripts represent dimensions in the model and prototype, respectively, while small letters represent their ratios, or the scale values. Continuing: q = discharge scale; a = area scale; e = scale of sand-grain diameters; r = hydraulic radius scale; etc.

---

[8] Lieut., Corps of Engrs., U. S. A.; Student, Command and Gen. Staff School, Fort Leavenworth, Kans.

The authors are to be congratulated for the able way in which they have handled a difficult subject and for their courage in daring to deviate from well beaten European paths. The writer has found that the same principles are suitable to investigations of navigation works in rivers[9] and has verified to his own satisfaction the feasibility of designing hydraulic models to preserve dynamic similarity under all conditions of operation.

C. E. GRUNSKY,[10] PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The experiments described in this paper, some of which it was the writer's privilege to have attended, were interesting in giving occular demonstration of the behavior of two vertical surfaces of liquids of different density in contact with each other when freed from restraint. However, the conditions at a lock when a gate between a fresh-water and a salt-water compartment is to be opened, were not reproduced at the model, and it is questionable whether the deductions made by the authors should not be subjected to further review. Personally, the writer does not think it worth while.

In the demonstration with the experimental model the water surfaces on both sides of the partition separating the compartments of different densities were at the same level. There was consequently greater aggregate pressure from top to bottom against the partition on the side of the denser liquid than against the other side. At a lock-gate—the device which is being studied—the opening of the gate does not take place until the total water pressures on the two sides are practically equal. This occurs when the fresh water attains a superelevation over the ocean water of about 1.3 per cent. In a lock with 40 ft of salt water on the sill, the superelevation of the water in the fresh-water compartment would be somewhat more than 0.5 ft.

At the surface of the salt water there would be a velocity head of about 0.52 ft impelling the fresh water against the salt water. At 20 ft above the gate-sill, the velocity head, expressed in fresh water, would be the same on the salt-water side as on the fresh-water side, and at the sill the velocity head, expressed in fresh water, would be 0.52 ft greater on the salt-water side.

---

[9] *Civil Engineering*, August, 1932, p. 467.

[10] Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif. Mr. Grunsky died on June 9, 1934.

Sudden removal of the partition, of course, would cause an over-run of fresh water in one direction, while there is an under-flow of salt water in the other direction, although necessarily somewhat checked in its velocity of flow by the superelevation of the fresh water, a factor which has not been taken into consideration by the authors.

It is an interesting fact that under certain physical conditions, such superelevation as here referred to may be fairly permanent in locations where there is a gradual transition from fresh water to ocean water. This fact was brought to the attention of the Federal and State engineers who were in charge of studies for a San Francisco Bay salt-water barrier, by the writer in 1931.

Take, for example, any long narrow tidal estuary in which there is a fair depth and considerable tidal movement. Here, as long as there is any material accession of fresh water, there will be a gradual approach, throughout a long stretch of estuary, from fresh-water density to ocean density. If, now, the great block of brackish water in such an estuary is regarded as a block of foreign material interposed between the fresh and the salt water—a gate, in other words, that may be 40 or 50 miles thick up and down stream—then it will at once be apparent that there can be no equilibrium unless the fresh water at the upper end of this block is at a higher level than the salt water at its down-stream end. The brackish water, in other words, has a gradient from its fresher to its saltier end. Despite this gradient, the area of brackish water will be in substantial equilibrium.

Take, for example, the Upper San Francisco Bay region and the delta of the Sacramento and San Joaquin Rivers. At the fall low-water stage of these rivers, brackish water fills Suisun Bay which lies at, or just below, their junction. Brackish water is pushed by the tide back and forth in the San Joaquin River for about 20 or 30 miles in a channel which for a long distance has depths exceeding 50 ft. In this long river stretch, and on down through Suisun Bay and the Straits of Carquinez, there is a gradual increase of water density from fresh water (specific gravity, 1.00) to ocean water (specific gravity, 1.026).

In the Straits of Carquinez below Suisun Bay the water has generally a maximum depth of from 50 to 60 ft. The tidal range here averages, at low stages, 5 to 6 ft, and tidal currents are strong. There is no pocketed salt water. Transition from the fresh to the salt is gradual throughout the stretch of water here under consideration. It follows, therefore, that in the lower delta of these rivers and through Suisun Bay to wherever full-strength ocean water penetrates, there will be an inclined stable water surface with a superelevation at up-stream points of about ($\frac{1}{2} \times 60 \times 0.026 =$) 0.8 ft.

Sea level, for example, approximated by mean tide at Stockton, Calif., above the reach of brackish water, but on the waters of the Lower San Joaquin River, will be about 0.8 ft higher than true sea level because of the depth (60 ft, or thereabouts) throughout which the lighter fresh water must offset the greater pressure of the salt water in the down-stream delta channels.

John B. Drisko,[11] Jun. Am. Soc. C. E. (by letter).—This paper is another striking example of the versatility of hydraulic models. It is also of great value in showing the necessity of a proper choice of model scales if correct results are to be obtained.

The authors introduce their Equation (1) as being equal to "the change of the momentum, $M V_0$, per second", thus ascribing the velocity of the wave front, $V_0 = \frac{dx}{dt}$, to the entire moving mass. This is a bold assumption. If it had been assumed that the velocity decreased slightly from the wave front back toward the undisturbed liquid (that is, in Fig. 6, from B toward Plane C-C), then the momentum of the moving slug $(= \int v\, dM)$ would have been less, yielding a higher value of V_0 in Equation (5). If a higher value of V_0 is correct, then the apparent agreement between the observed results and the (low) values of Equation (5) may be due to the fact that the observed "initial velocity" was measured over a distance long enough to permit of considerable viscous retardation.

Furthermore, if the authors' assumption regarding the velocity is retained, then the kinetic energy of the entire moving mass is,

$$\frac{1}{2} M V^2_0 = \frac{1}{2}\, x\, d\, \frac{w}{g} (G_1 + G_2)\, V^2_0$$

Equating this to the decrease in potential energy (which is $< \frac{1}{4}\, w\, s\, d^2\, x$ since the center of gravity of the salt-water slug, $COBC$, has dropped from a height, $\frac{d}{2}$, to a height greater than $\frac{d}{4}$) gives a result that is quite independent of x, namely, $V_0 < \sqrt{\frac{1}{2}\, \frac{s\, d\, g}{(G_1 + G_2)}}$. This does not agree with observation or with previous calculation and, therefore, the average velocity of the entire moving slug must be less than V_0.

It is interesting to note that Equation (5) is merely the usual equation for the velocity of a wave of translation, $v = \sqrt{gh}$, with the term, $\frac{s}{(G_1 + G_2)}$ included to compensate for the conditions of specific gravity and for the fact that both salt water and fresh water are being accelerated. The wave height, h, is, in this case, equal to $\frac{d}{2}$. Whether or not the absolute value of V_0 calculated by the authors is correct, the form of the expression seems rational, and hence the validity of the model law as derived is in no way affected.

The authors describe the action of a lock full of salt water when released into a larger body of fresh water. The unbalanced force, before release, is the excess of the static pressure on the gate. The distribution of this excess pressure is as shown in Fig. 15. It would be interesting to investigate the reverse condition in which the unbalanced force is in favor of the fresh water, as shown in Fig. 16. As before, the pressure distribution is triangular, but the base of the pressure triangle is at the surface of the salt water instead of at the bottom. The extra height of the fresh water shown could be replaced by a restrained float, in order to reduce to a minimum the quantity of fresh water that would immediately flow over the surface of the salt water.

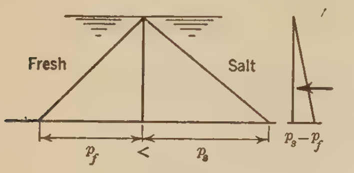

FIG. 15

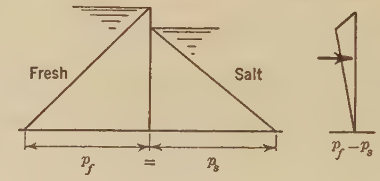

FIG. 16

The statement of the authors, in the last paragraph under "Theory" that "* * * a drop of the surface at any place would have to be made up by a rise of the surface at some other place; * * * and, therefore, no drop of the surface could furnish the energy required to set water in motion", is confusing. If salt water drops and fresh water rises, there is a net loss of potential energy which is available for conversion to kinetic energy.

The derivation of the model law is clear and logical. Of particular significance is the statement following Equation (13) that its physical meaning is that "the inertia, pressure, and friction forces in the prototype must be reduced in the same ratio in the model." Inertia, pressure, and friction are the major forces in this particular problem, and, for true similarity, they must all be given due regard. With some types of models it is difficult or impossible to represent two types of forces in the same model. In the case of ship models, for instance, the skin friction resistance and the wave or form resistance vary according to different laws. In testing ship models, the total resistance is measured, the frictional resistance is calculated empirically, and the difference gives the form resistance of the model. If two types of forces cannot be properly represented in the same model, two models constructed to different scales are sometimes used. In each model, one particular phase of the problem is studied, with little or no regard to the other.

In this paper, the authors have shown how all the essential conditions for a proper simulation of the motion of salt water through fresh may be represented in a single model which will yield correct results.

G. H. KEULEGAN,[12] ESQ. (by letter).—The derivation of model laws in certain cases of fluid motion is effected readily by means of the energy equation. The motion of salt water through fresh presents a clear example. The method, in this particular case, has the advantage of directness and affords a more intimate understanding as to the restrictions to be imposed on the phenomena for a workable model relation than the method of dimensional analysis, for example. This understanding no doubt can also be derived by the method of differential equations; but if that method is used, the rigorous computations are somewhat involved, since it is then necessary to use separately the Eulerian and Lagrangian equations expressed differently for the two liquids, with the additional boundary conditions to be satisfied at the points where these liquids are in contact. The authors use the Eulerian equation in the first stages of the motion (Equations (1) and (9), inclusive). They then revert to the Lagrangian equation, applying it only to the salt water, whereas for a rigid solution of the problem, they should use also a similar equation for the fresh water, together with the boundary conditions existing at the surface of contact. The derivation here presented corrects this defect in the derivation of the authors. It differs from that of the paper only in the definitions of the effective kinematic viscosity and the effective salinity occurring in the expressions of the model law.

---

[12] Associate Physicist, Bureau of Standards, U. S. Dept. of Commerce, Washington, D. C.

Certain assumptions are necessary in the present derivation to obtain the law practically in the same form as that given by the authors. It will be assumed first that the motion is essentially a two-dimensional one. In other words, the width of the channel is of the same order as its depth, and the major part of the dissipation of energy arises from the sharp velocity gradient at the boundary separating the two liquids. In this connection it is scarcely necessary to state that the question of surface tension does not enter, since the two liquids mix. On the other hand, the mixing at the surface of separation due to diffusion takes place at a much slower rate than the velocities involved in the flow of the water. Since the motion is assumed to be two-dimensional, unit width of the channel will be assumed in making the energy computations. Other assumptions will be stated as occasion arises.

In addition to the notation of the paper, ρ_1 and ρ_2 denote, respectively, the densities of the salt water and of the fresh water. Suppose that at the time, $t = 0$, the lock holding the salt water is opened and the salt water (shown as the cross-hatched area) has advanced at the time, T, to the position shown in Fig. 17. At the point, P_1, an element of salt water has the mass, $\rho_1\,dX\,dY$, and the elevation, Y_1. Initially, this element occupied the position, P_0, in the lock at the time, $t = 0$, and had the elevation, Y_0. Accordingly, the system suffers a decrease of potential energy,

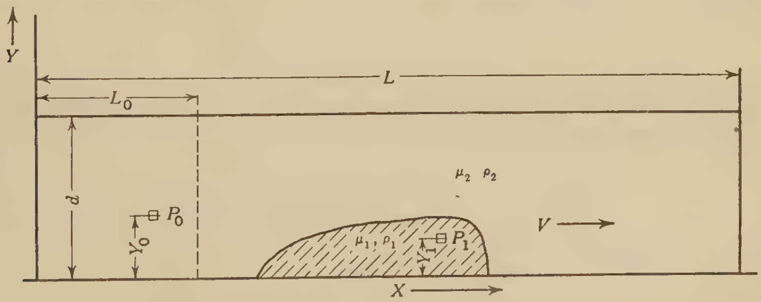

FIG. 17

$$dW = g\,(Y_0 - Y_1)\,(\rho_1 - \rho_2)\,dX\,dY \ldots\ldots\ldots\ldots\ldots (20)$$

arising from this transfer. Thus, at the instant, T, the entire system has suffered a loss of potential energy of amount,

$$W = g\,(\rho_1 - \rho_2) \int_{\text{vol.}} (Y_0 - Y_1)\, dX\, dY \ldots\ldots\ldots\ldots (21)$$

Here the integration is carried out for the region occupied by the salt water. Using the theorem of the mean, Equation (21) becomes,

$$W = g\,(\rho_1 - \rho_2)\,\alpha\, d \int_{\text{vol.}} dX\, dY$$

in which $\alpha\, d$ represents the space average of the drop, averaged over the initial salt-water volume. It follows that,

$$W = \alpha\, g\,(\rho_1 - \rho_2)\, d^2 L_0 \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

since the volume integral is equal to the volume of the lock. It is to be observed that α as derived herein is a pure number having a value which depends on T. Practically, however, α changes very slowly with time. The authors have shown that initially it has the value, 0.25.

This decrease in the potential energy of the system is compensated in part by the increase in the kinetic energy of the system. The remaining part represents energy that is dissipated during the time interval, T. In the computation of the kinetic energy and of the dissipation as well, the effect of the vertical component of the velocity will be assumed to be negligible. With this assumption in mind, the kinetic energy of the system at the time, T, is,

$$K\,E = \tfrac{1}{2} \int_0^d \int_0^{L_1} \rho\, V^2\, dX\, dY$$

in which, V is the velocity at any point along the channel at the time, T. Since ρ does not have the same value throughout, one may write, using the theorem of the mean:

$$K\,E = \tfrac{1}{2}\,\gamma\,\rho_m \int_0^d \int_0^{L_1} V^2\, dX\, dY \ldots\ldots\ldots\ldots\ldots (23)$$

in which, ρ_m represents the value of the densities averaged over the volume of the moving liquids; that is,

$$\rho_m = \frac{\rho_1 + \rho_2}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

and γ represents a number the value of which depends on T. The integrated dissipation function, on the other hand, is,

$$2\,F = \int_0^T \int_0^d \int_0^{L_1} \mu \left(\frac{dV}{dY}\right)^2 dX\, dY\, dt$$

in which, $2F$ represents the energy of dissipation.[13] Since the viscosity does not have the same value throughout, one may write, using again the theorem of the mean:

$$2\,F = \beta\,\mu_m \int_0^T \int_0^d \int_0^{L_1} \left(\frac{dV}{dY}\right)^2 dX\, dY\, dt \ldots\ldots\ldots\ldots (25)$$

---

[13] Lamb's "Hydrodynamics," Fourth Edition, p. 549.

in which, μ_m represents the value of the viscosities, averaged over the volume of the moving liquids; that is,

$$\mu_m = \frac{\mu_1 + \mu_2}{2} \ldots\ldots\ldots\ldots (26)$$

μ_1 and μ_2 being the viscosities of the salt water and of the fresh water, respectively, and β representing a number the value of which depends on T. Although rigorously β and γ are dependent on time, their variation with time will be small when the differences, $\mu_1 - \mu_2$ and $\rho_1 - \rho_2$, are small.

The principle of the conservation of energy gives,

$$\alpha\, g\,(\rho_1 - \rho_2)\, d^2 L_0 - \beta\, \mu_m \int_0^T \int_0^d \int_0^{L_1} \left(\frac{dV}{dY}\right)^2 dX\, dY\, dt$$
$$- \tfrac{1}{2}\, \gamma\, \rho_m \int_0^d \int_0^{L_1} V^2\, dX\, dY = 0 \ldots\ldots\ldots\ldots (27)$$

Introducing the initial velocity, V_0, of the front of the salt-water wave and writing:

$$x = \frac{X}{L_0};\ y = \frac{Y}{d};\ \tau = \frac{t}{T};\ L_1 = m L_0;\ v = \frac{V}{V_0};\ \nu = \frac{\mu_1 + \mu_2}{\rho_1 + \rho_2};\ \text{and } s = \frac{\rho_1 - \rho_2}{\rho_1 + \rho_2},$$

the energy equation (Equation (27)) becomes,

$$2\, \alpha\, g\, s\, d - \beta\, \frac{V_0^2\, T\, \nu}{d^2} \int_0^1 \int_0^1 \int_0^m \left(\frac{dv}{dy}\right)^2 dx\, dy\, d\tau$$
$$- \gamma\, \frac{V_0^2}{2} \int_0^1 \int_0^m v^2\, dx\, dy = 0 \ldots\ldots\ldots\ldots (28)$$

The corresponding equation for the model is,

$$2\, \alpha'\, g'\, s'\, d' - \beta'\, \frac{V_0'^2\, T'\, \nu'}{d'^2} \int_0^1 \int_0^1 \int_0^m \left(\frac{dv}{dy}\right)^2 dx\, dy\, d\tau$$
$$- \gamma'\, \frac{V_0'^2}{2} \int_0^1 \int_0^m v^2\, dx\, dy = 0 \ldots\ldots\ldots\ldots (29)$$

If T' of the model is the time corresponding to T of the prototype, the integrals in Equations (28) and (29) are equal in value, and, also, $\alpha = \alpha'$, $\beta = \beta'$, and $\gamma = \gamma'$, approximately, since vertical velocities are neglected. Hence, the following relations are valid:

$$\frac{g\, s\, d}{g'\, s'\, d'} = \frac{V_0^2\, T\, \nu\, d'^2}{V_0'^2\, T'\, \nu'\, d^2} = \frac{V_0^2}{V_0'^2} \ldots\ldots\ldots\ldots (30)$$

If T and T' are corresponding times, it can be shown that $T = \dfrac{L_0}{V_0}$, $T' = \dfrac{L'_0}{V'_0}$, so that instead of Equations (30), the following may be written:

$$\frac{g\, s\, d}{g'\, s'\, d'} = \frac{\nu\, V_0\, L_0\, d'^2}{\nu'\, V'_0\, L'_0\, d^2} = \frac{V_0^2}{V_0'^2} \ldots\ldots\ldots\ldots (31)$$

and, therefore,

$$\frac{\nu\, L_0}{g^{0.5}\, s^{0.5}\, d^{2.5}} = \frac{\nu'\, L'_0}{g'^{0.5}\, s'^{0.5}\, d'^{0.5}} = \kappa \ldots\ldots\ldots\ldots (32)$$

in which, κ is a constant. This agrees in form with the model law obtained by Messrs. O'Brien and Cherno, except that, in Equation (32), ν represents the ratio of $\mu_1 + \mu_2$ to $\rho_1 + \rho_2$, and s the ratio of $\rho_1 - \rho_2$ to $\rho_1 + \rho_2$; whereas, in the law as stated by them, ν is the kinematic viscosity of the salt water and s the difference between the specific gravity of the salt and fresh water.

The foregoing derivation of the model law has been presented primarily because of its theoretical significance. In experiments in which the differences, $\rho_1 - \rho_2$ and $\mu_1 - \mu_2$, are small, as is the case here, and in which the uncertainties in the observation of the position of the salt-water wave are relatively large, it makes little difference whether the model law developed by the authors, or the law developed in this discussion, is used. Although the authors do not discuss their errors of observations, it seems probable that these were large enough to make it impossible to distinguish which model law agrees better with the experimental data.

MORROUGH P. O'BRIEN[14] AND JOHN CHERNO[15], ASSOC. MEMBERS, AM. SOC. C. E. (by letter).—In regard to Lieut. Vogel's suggestion that the symbols used in model work be standardized, the writers agree heartily. The symbols in this paper were changed to conform to those of the Society's Special Committee on Irrigation Hydraulics, in so far as was possible.

The experiments under discussion were made for two purposes, as follows: (1) To study the motion of salt water through fresh water, particularly with reference to the dilution of the salt water during the process; and (2) to discover the model law for this phenomenon which was then to be used to design a model of a part of San Francisco Bay.

This paper is concerned only with the second objective, and whether the water surfaces were equalized on the two sides of the gate does not affect the validity of the resulting model law. Mr. Grunsky is not correct in assuming that lock-gates or lock operation was being studied in these tests. Conditions in actual locks are further complicated by the overfilling of the chamber resulting from the inertia of the water in the culverts; by the non-uniform distribution of salinity in the lock chamber; and by the residual motion of the water in the lock resulting from the filling process. While none of these factors is of major importance in the general characteristics of the motion after the gate is opened, they may disturb the motion in an actual lockage, and the formulas given in the paper must not be used blindly.

The writers cannot agree to Mr. Grunsky's "substantial equilibrium" in the brackish waters of an estuary (disregarding tidal effects) unless the word, "substantial," is changed to "dynamic" or "statistical." The surface gradient would cause water near the surface to flow down stream and the excess pressure due to the salt water would cause an under-flow up stream. The salt water, being diluted with the overlying fresh water, will become less and less brackish during its up-stream movement and, at the same time, the fresh water moving down stream will increase in salinity. As much of the surface gradient as is not used to move the net river flow will serve to maintain these two opposed currents.

---

[14] Assoc. Prof., Mech. Eng., Univ. of California, Berkeley, Calif.

[15] Sacramento, Calif.

In a tidal estuary it is difficult to measure these currents, but it is known from current meter measurements that "the flood tide comes in at the bottom;" that is, the ebb current turns to flood current sooner at the bottom than at the surface, the time lag being as much as two hours in some cases. This agrees with the conception of two separate and opposed currents. The surface gradient in a tidal estuary resulting from varying salinity cannot be obtained by simply comparing the elevation of mean sea level at two points because a gradient would exist also with no river inflow, and with constant salinity. This gradient must be great enough to discharge the tidal prism at ebb tide, and this same surface slope tends to decrease the volume of the flood tide. The measured gradient in a tidal river comprises the gradients resulting from net discharge, varying salinity, and tidal flow. Mean sea level, as defined by the U. S. Coast and Geodetic Survey, at Stockton, Calif. (92 miles from the Golden Gate) was 1.5 ft above mean sea level at the Golden Gate in August, 1930; in the same month, mean sea level at Dumbarton Bridge (33 miles from the Golden Gate), was 0.4 ft above the same datum in spite of the fact that there is practically no variation in salinity and no fresh-water inflow in the southern arm of San Francisco Bay.

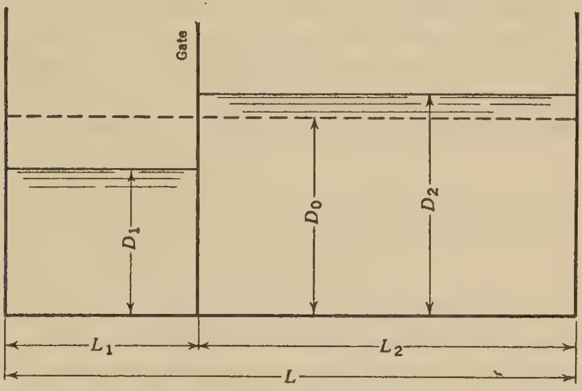

Fig 18

Some experiments were made that have a bearing on Mr. Drisko's question regarding the effect of different water-surface elevations on the two sides of the gate. Referring to Fig. 18, the surfaces will ultimately come to rest at a depth, D_0, given by,

$$D_0 = \frac{1}{L}(D_1 L_1 + D_2 L_2) \quad \dots\dots\dots\dots (33)$$

If the gate is moved to the left (for the conditions shown) until this depth, D_0, is obtained, the length of the lock will be,

$$L_0 = L_1 \frac{D_1}{D_0} \quad \dots\dots\dots\dots (34)$$

If the modulus, K, is computed from these values of L_0 and D_0 and the actual S_0, the velocity curve drawn using Fig. 13 agrees quite well with the experimental values, particularly during the later stages of the motion.

In reply to Mr. Howland's inquiry, the surface slope shown in Fig. 6 existed at the heads of the fresh-water and salt-water waves. Between the two, the interface was practically horizontal provided the lock was long enough (compared with its depth) to make this surface form possible for any length of time. After fresh water reached the closed end of the lock, the salt-water slug had the form shown in Fig. 7. The center of gravity of the salt water moves toward the right, but the edges of the salt slug tend to spread in all directions from the center of gravity. Spreading at the front edge is resisted by the internal friction, but spreading backward reduces the velocity, thus giving the peculiar shape shown. After this shape is reached, the motion does not continue primarily under the action of a pressure gradient, as suggested by Mr. Howland, but rather on account of inertia, until kinetic energy is dissipated.

Motions at C and E, such as described by Mr. Howland, were not observed. Floats placed on the surface to the left of C acquired full velocity toward the left very abruptly, and the same phenomenon was observed by one of the writers in the Ballard Locks, at Seattle, Wash.

The significance of K may best be grasped by writing:

$$K' = \frac{L_0\,\nu}{g^{0.5}\,s^{0.5}\,d^{2.5}} \propto \frac{\nu}{V_0\,d}\left(\frac{L_0\,d\,\dfrac{w}{g}\,s}{\dfrac{1}{2}\,w\,d^2\,s}\right) = \frac{1}{R}\left(\frac{M_s}{F_s}\right) \quad \text{..........(35)}$$

in which, M_s is the mass of salt (not salt water; note that the only net effect of opening the gate is a displacement of the salt toward the right); F_s is the force causing motion; and, R is a Reynolds number. The Reynolds number indicates the relative importance of inertia and friction forces, large values of R corresponding to motions predominated by inertia effects and the reverse. The factor, K', therefore, becomes large when a large mass of salt is to be moved by a small force under conditions conducive to large frictional resistance. The curves corresponding to large values of K in Fig. 7 show a rapid decrease in velocity for precisely this reason. (In tests of this type larger dilution values can be obtained if K is small.)

It should be pointed out here that μ was not defined as the absolute viscosity (see following Equation (10)), but as a coefficient of internal friction and that the conclusions state that the internal friction behaves in a manner similar to the viscous force of laminar flow, but nothing was said as to the value of μ or ν. The theory of turbulent flow as developed by Prandtl, von Karman, and G. I. Taylor expresses the frictional resistance in terms of transfers of momentum or vorticity which results in a "mechanical viscosity" having properties similar to the viscosity of laminar flow. In fact, in the original draft of the paper, ν was called the "mechanical viscosity," but the term was dropped to avoid lengthy explanation of its significance. The important point is that the dilution or mixing is an integral part of the mechanism of turbulent friction and the existence of turbulent mixing was assumed throughout. A model law which represents the motion accurately, particularly the dissipative effect of internal friction, must also represent the mixing. For this reason, the use of mercury in a model is perhaps inadmissible, but the point should be investigated.

Dr. Keulegan's more rigorous derivation of the model law from the standpoint of energy is interesting and it is unfortunate that the accuracy of the experiments does not warrant a comparison of this model law with the simplified law proposed by the writers. Equation (5) was originally derived from the standpoint of energy, and this derivation is perhaps preferable to the momentum method, which is open to criticism from a mechanical standpoint.

Mr. Howland suggests that the motion be considered as the result of the action of a force equal to $\frac{1}{2}\ w\ s\ d^2$ tending to move the entire mass of water between Sections C-C and E-E toward the right, and infers that this tendency must be accompanied by a vertical movement of the free surface. Apparently, he overlooks the fact that the salt water to the left of C has a downward acceleration which reduces the pressure below the hydrostatic pressure corresponding to the depth. Pressure adjustments are propagated with the velocity of sound, which in the present problem is equivalent to occurring instantaneously. As soon as motion of salt water begins, vertical accelerations at C reduce the pressure and the fresh water begins to move toward the left.

In obtaining Equation (2), the force acting was based upon the difference in density, and the momentum was taken as the arithmetic rather than the vector sum of the momenta of the salt and fresh water, even though the two are oppositely directed. This is necessary because the liquid between Sections C-C and E-E is not a free body in the ordinary sense, but rather the salt or fresh water moves subject to the restraint imposed by the presence of the other fluid. The condition is entirely analogous to the oscillations of liquid in a **U**-tube manometer. The activating force results from the unbalance of the columns but the momentum is the arithmetic sum of the momenta in the two legs and not the vector sum. If the vector sum of the momenta was taken in Equation (2), the initial velocity, V_0, would be found to depend only on the depth and the acceleration of gravity and would be independent of the difference in density. Equation (5) can also be obtained by considering the salt (not salt water) as a free body of weight, $w\ s$, and mass, $\frac{w}{g}\ (G_1 + G_2)$ per cu ft. This method is reasonable since the net effect of opening the gate is simply a transfer of salt toward the right.

WIND STRESS ANALYSIS SIMPLIFIED

BY L. E. GRINTER,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. FRANCIS P. WITMER, ELMER K. TIMBY, N. A. RICHARDS, JOHN B. LETHERBURY, FREDERICK MARTIN WEISS, RAYMOND C. REESE, A. FLORIS, ROBINS FLEMING, J. D. GEDO, H. V. SPURR, JOHANNES SKYTTE, JOHN B. WILBUR, AND L. E. GRINTER.

SYNOPSIS

One of the most difficult problems that the structural engineer must solve is the analysis of stresses in a continuous frame in which joint displacements occur. In many cases, since the loading is fixed, the analysis does not involve placing loads for maximum stress. The calculation of wind moments in tall building frames is such a problem.

It is the purpose of this paper to present a method, or rather a system of analysis, by which such frames may be analyzed with satisfactory accuracy in a simple manner and in a fraction of the time required by most exact or nearly exact methods. This simplified method of analysis is made dependent upon the system of balancing fixed-end moments introduced[2] by Hardy Cross, M. Am. Soc. C. E. Accordingly, the application of the method requires the use of only the simplest arithmetic. The importance of this fact is great since the designer's mind is left largely free to study the matter of proportioning the structure.

METHODS IN COMMON USE

An exact analysis of a continuous frame, such as a wind bent, has usually required the solution of a group of simultaneous equations, which is a rather tedious process even when simplified to the greatest possible extent. The

---

NOTE.—Presented at the meeting of the Structural Division, New York, N. Y., January 19, 1933.

[1] Prof., Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

[2] "Analysis of Continuous Frames by Distributing Fixed-End Moments," *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

most usable of these older methods is probably the Slope Deflection Method as advanced by Wilson and Maney.[3] Simplifications of the slope deflection method and of other exact methods have been proposed. Usually, these simplifications have involved the idea of neglecting the effect of moments in one story upon the moments in all other stories except those adjacent to the one under consideration. The approximate methods that resulted were entirely satisfactory except for the time consumed in the analysis. Particularly in the case of wind stresses in tall building frames the time required for an exact or nearly exact analysis has seemed excessive, and engineers have continued to make wide use of the so-called statically determinate methods. This fact is surprising because these methods have been shown to be in error as much as 100%, even for quite regular buildings.

To date, the most usable method of wind stress analysis, which also can claim to be more than a rough estimate, is that suggested by Ross and Morris.[4] This method is both fast and simple to apply, but gives results that seem to be too greatly in error for careful design. In several cases in the two analyses presented by those writers (the Wilson-Maney bent and the American Insurance Union Building), the moments are shown to vary from the correct values by from 15 to 48 per cent.

The most recently suggested method of analyzing continuous frames is that made by Professor Cross.[2] The Cross method of balancing fixed-end moments is directly applicable to all frames when translation occurs at none of the joints. It is fast and simple, and produces any degree of accuracy desired. The writer considers it to be the most satisfactory method yet proposed for the analysis of frames in which the joints do not move. For cases in which joint translations occur, Professor Cross suggests a method of balancing shears, but this, like the other exact methods of caring for joint movements, requires considerable time. Certainly, for the case of wind stress analysis the time required will be found to be excessive.

General Method of Successive Corrections

The writer has suggested a general method of analyzing continuous frames for fixed loads, which he has been in the habit of calling "Successive Corrections."[5] This method was re-stated and examples of its application to wind stress analysis have been presented by Professor Morris.[6] The first step in the general method of successive corrections is to balance fixed-end moments. A simplification is possible in certain cases and this is the "simplified method of wind stress analysis" suggested in this paper. The simplified method is also applicable to certain structures other than building frames, notably bents, open web trusses, and articulated trusses for secondary stress analysis.

[4] "The Design of Tall Building Frames to Resist Wind," by Albert Ward Ross, Jr., Jun. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E,, May, 1928, Papers and Discussions, p. 1595.

[5] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 11.

[6] *Loc. cit.*, p. 66.

The general method of successive corrections is re-stated herein to form a background for the presentation of the simplified method, as follows:

(*a*) The structure is allowed to deflect under the loads while the joints are fixed against rotation, and the fixed-end moments are calculated.

(*b*) The fixed-end moments are balanced around the joints until each joint is in equilibrium; that is $\Sigma M = 0$ at each joint. During this process no translations of the joints are allowed. This step is the same as in the Cross method of balancing fixed-end moments.

(*c*) From the balanced moments of Step (*b*) the total shears are determined, and from the difference between these shears and the true shears the artificial restraining forces at the joints are found. (There must be restraining forces since the deflections of the structure as produced in Step (*a*) are not the true deflections.)

(*d*) The joint forces found by Step (*c*) are eliminated by applying equal and opposite joint forces.

(*e*) The structure is allowed to deflect with fixed joints under the action of this new force system, fixed-end moments are calculated, joint moments are balanced, and a second set of joint restraints is computed. It will be found that this second set of joint restraints is smaller and of less importance than the first set.

(*f*) The process is repeated until a final set of joint restraints is determined that is small enough to neglect entirely.

(*g*) The final moments are obtained by adding algebraically the successive sets of balanced moments determined from the original applied loads and the several sets of forces that balance the artificial joint restraints.

The foregoing explanation of the full method of successive corrections is given in detail, in order to make the process clear. When stated in this manner, the reader should visualize clearly a physical action of the structure that corresponds to each step of the process. In practical applications the method may be simplified considerably. Since the first balancing of fixed-end moments is disrupted by the application of a second set of fixed-end moments, it is clear that the first balancing need not be carried to its normal conclusion. In fact, it would be a waste of time to balance the individual joints more than twice before releasing joint restraints. Professor Morris[6] has suggested releasing joint restraints after each balancing of the individual joints, which is entirely satisfactory.

Furthermore, there is an obvious simplification in the practical application of Steps (*c*), (*d*), and (*e*), that is, in releasing joint restraints. It is unnecessary actually to calculate the joint restraints at all, because the difference between the sum of all balanced column moments in a given story and the sum of all the original fixed-end moments is equal to the sum of the second set of fixed-end moments to be applied in this story. This total fixed-end moment is to be divided among the columns in proportion to their *K*-values. Nevertheless, it is of importance that one realize the full significance of this simplification.

The Simplified Method

In the method of successive corrections, the first set of balanced joint moments would have been the true final moments if the first set of artificial joint restraints had been negligible. Moreover, the first set of joint restraints would have been negligible if the deflections of the structure with joints fixed against rotation had been essentially the same as the true deflections. In other words, if the true deflections of the joints can be guessed at, estimated, or actually calculated, it is permissible to force the structure into this deflected position with fixed joints. Then one can calculate the fixed-end moments caused by these deflections and balance the joint moments. If the estimated deflections are reasonably correct, the joint restraints will be found negligible, and the first set of balanced moments may be taken as the final moments. When the first set of joint restraints is too large to neglect, but is still small in comparison with the actual loads, the moments may be corrected approximately. This is accomplished by assuming that there will be no change in the location of the points of contra-flexure in the members. Hence, the final column moments are obtained simply by multiplying the first balanced moments by the ratio of the true shear to the computed shear in that story. Final girder moments are obtained by dividing the sum of the corrected column moments at each joint between the girders in the same ratio as that of the uncorrected girder moments. An outline of this simplified method is, as follows:

(1) Guess at, estimate, or calculate the displacement of each joint of the frame as caused by the applied loads.

(2) Compute the fixed-end moments in the members as caused by these movements. If the translation is horizontal, there are no fixed-end moments in horizontal members.

(3) Balance the moments in succession at all joints until the joints are fully balanced; that is, until $\Sigma M = 0$ at each joint.

(4) Compute the total shear in each story from the balanced moments. The difference between these shears and the real shears caused by the loads is a fair indication of the error in the moments.

(5) Determine the final column moments by proportion, using the relation:

$$\text{Final moment} = \text{Balanced moment} \times \frac{\text{True shear}}{\text{Calculated shear}}$$

(6) Determine the final girder moments by dividing the sum of the corrected column moments at each joint between the girders in the same proportion as that of the uncorrected girder moments.

When the calculated shear is within 10% of the true shear, one need have no fear but that the final moments will check the true moments within a range of error of about 5% when proportioned as indicated in Steps (5) and (6). This factor of 5% is intended to apply to moments of average intensity. A particularly small moment may be in error by 6 or 7 per cent. In several cases the writer has been able to estimate the deflections of building frames with sufficient accuracy so that the calculated shears have been within 6%

of the true shears, and when corrected by proportion the final moments have checked the true moments within 3%, or less. When the frame is irregular, larger errors are naturally to be expected.

The remainder of this paper will be devoted to a development and application of simple methods of estimating the absolute or relative joint deflections of frames before the division of the total moment among the members is known. Relative deflections are as satisfactory as absolute deflections since the final moments are obtained by proportion. Examples of the application of the simplified method to several continuous frames will be given. The examples chosen have previously been analyzed in the literature of this field so that the percentages of error may be studied. The major emphasis is thrown upon the analysis of wind moments in tall building frames because this is the most important of all problems in the field of continuous frames and the one that has been most neglected.

RE-STATEMENT OF THE PROCESS OF BALANCING MOMENTS

In the process of balancing moments, one starts with a set of fixed-end moments in the members. These moments may be caused by intermediate loads or by joint translations. Those caused by intermediate loads are calculated as in any fixed-end beam. When joint translations occur, the fixed-end moments may be computed as follows: In Fig. 1, the deflection at B from a tangent to the elastic curve at A is equal to the statical moment of the $\frac{M}{EI}$ diagram from A to B about B. Therefore,

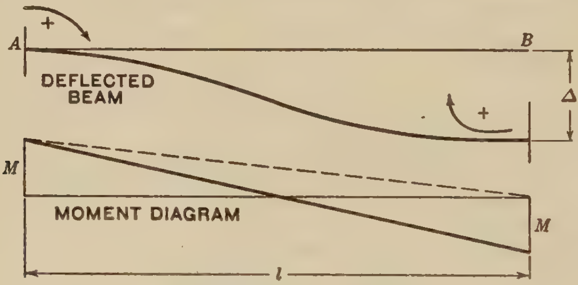

FIG. 1.—JOINT TRANSLATION.

$$\Delta = \frac{Ml}{2EI} \times \frac{2}{3}\, l - \frac{Ml}{2EI} \times \frac{1}{3}\, l = \frac{Ml^2}{6EI} = \frac{Ml}{6\,EK} \quad \ldots\ldots\ldots(1)$$

and the fixed-end moment is,

$$M = \frac{6\,EK\,\Delta}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

The question of signs must be given careful consideration since the sign convention adopted is different from that used by Professor Cross. However, a single statement of this sign convention will cover all cases: When an end moment tends to rotate a joint in a clockwise direction, that moment is always considered positive. In Fig. 1, since the moment in the member, $A\,B$, at A tends to rotate the joint clockwise, this moment is positive; also, the moment at B in the member, $A\,B$, tends to rotate Joint B clockwise, and, therefore, this moment is positive. The deflected shapes of members with the usual conditions of fixed-end moments are shown in Fig. 2. It is possible to find combinations of the cases shown, as, for instance, normal translation plus intermediate loads.

When the fixed-end moments in all members have been determined, the joints are balanced in any desired succession until each joint is eventually freed from any restraining moment. The sum of the moments recorded around any joint at one time is equal to the total unbalanced moment. The individual moments are in proportion to the K-values of the members meeting at the joint. The balancing moments to be recorded at any one time around a joint are of the same sign and of opposite sign to the unbalanced moment.

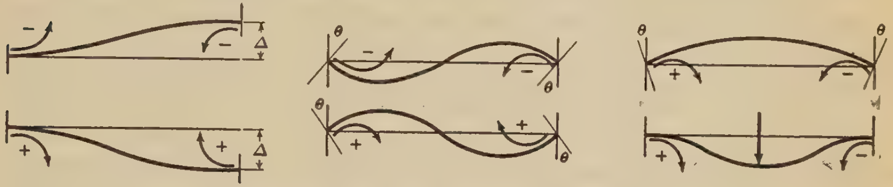

FIG. 2.—SIGNS OF FIXED-END MOMENTS.

Carry-over moments are of the same sign as the balancing moments. They are equal numerically to 50% of the balancing moments if the members are of uniform cross-section from end to end. The algebraic sum of the original fixed-end moment, the balancing moments, and the carry-over moments for any member at a given joint represents the final balanced moment at that end of that member. When this sign convention is used, the algebraic sum of all final balanced moments around a joint is equal to zero; that is, the joint is in static equilibrium.

SECONDARY STRESSES IN TRUSSES

The most obvious application of the simplified method of analysis is in computing the secondary stresses in a truss. In this structure it is not necessary to guess at, or estimate, the deflections because they are caused almost entirely by the direct stresses and may be calculated directly. The computations for deflections may be made either by the Williot-Mohr diagram, or by the algebraic methods of virtual work or elastic weights. The relative deflection of the two ends of each member taken normal to its direction may be obtained from these data, and the fixed-end moments may be calculated by use of Equation (2).

The final secondary moments are obtained by balancing moments around the joints as in any other frame. The final balanced moments are slightly in error because of the existence of small joint restraints. If one is interested in the magnitude of these joint forces, they may be calculated.

As an example of the application of the method, the secondary moments are computed in Fig. 3 for a simple truss analyzed[7] by M. S. Ketchum, M. Am. Soc. C. E. It will be seen that the moments calculated by the simplified method check Dean Ketchum's results closely. The check would naturally have been exact if inaccuracies of slide-rule and graphical computations had not entered into the work. The shears producing the joint restraints are also calculated from the secondary moments given by Dean Ketchum, and are given in Fig. 3 (*c*). The largest joint force is 156 lb., acting downward at *C*. If the members have reasonable areas of cross-section, this force is considerably less than 1% of the load that would cause the assumed direct stresses in the members. Accordingly, the effect of the artificial joint restraints is negligible in secondary stress analysis and is properly omitted in making such computations.

[7] "Steel Mill Buildings," by M. S. Ketchum, M. Am. Soc. C. E., Fourth Edition, 1921, p. 309.

SINGLE-STORY BENTS

All single-story bents may be analyzed by the simplified method without the introduction of any error from neglected joint restraints. Since bents of this kind usually are either unsymmetrical, unsymmetrically loaded, or loaded both vertically and laterally, it becomes necessary to make two separate analyses. Any lateral joint restraint at the top of the bent that appears when balancing fixed-end moments produced by the intra-panel loads (side lurch prevented) is reversed in direction and added algebraically to the real lateral force at the top of the bent. Then, the fixed-end moments produced by this combined lateral force are balanced. A direct proportion exists between these balanced moments and the true moments produced by the lateral force. An explanation may be found in the fact that a single-story bent is limited to one possible type of lateral deflection; that is, side lurch. Hence, the moments are directly proportional to the lateral deflection. The bent will have its proper lateral deflection when the moments are adjusted by proportion so that the bent is in horizontal equilibrum. Final moments are obtained by adding algebraically the moments produced by intra-panel loads and side lurch.

THE MULTIPLE-STORY WIND BENT OF IDEAL PROPORTIONS

As an introduction to the study of wind moments in the tall building frame, the application of the simplified method to the analysis of a tall wind bent of theoretical proportions will be considered. This single-bay structure has two identical columns in each story and any number of stories of constant height. The *K*-values of the columns and girders increase from the top downward in direct proportion to the story shears.

When fixed-end moments caused by the wind shears are balanced, points of contra-flexure will be found at the mid-height of each column and at the center of each girder. The story shears obtained from the balanced moments will be found to bear a constant ratio to the wind shears. Hence, final moments may be obtained by direct proportion. An explanation is found in the fact that the joint restraints, if determined, would form a force system similar in all respects to the original force system. Accordingly, points of contra-flexure would not shift under the application of this second force system. (The local effect of base fixation is not considered here.)

(c) FINAL MOMENTS AND SHEARS CAUSING JOINT RESTRAINTS

FIG. 3.—SECONDARY STRESS ANALYSIS BY SIMPLIFIED METHOD.

It is significant that the side lurch is constant for each story of this bent either when joints are free to rotate or when they are fixed against rotation. The two deflection diagrams may be represented by two straight lines of different slope. A correspondence of deflection diagrams is necessary if exact final moments are to be obtained from the first balanced moments by direct proportion.

WIND STRESSES IN TALL BUILDING FRAMES OF REGULAR PROPORTIONS

A tall building frame will not follow the ideal proportions of a wind bent exactly, but it is of interest that these proportions are followed closely enough so that many buildings approach a straight-line deflection curve under the action of wind loads. With this information as a background, it is possible to set up a system for analyzing wind moments in tall building frames that may be applied to any frame and that is extremely simple when applied to a frame that has a smooth deflection diagram.

First, the assumption is made that the deflections in all stories are in proportion to the story heights. This statement is identical with the mathematical relation, $\frac{\Delta}{h} = C$, in which, Δ and h represent, respectively, the increment of side deflection and the height of any story, and C is a constant. It has been shown that the fixed-end moment is determined from the relation,

$$M = \frac{6\,E\,K\,\Delta}{h} \qquad \text{(3)}$$

Therefore, if $\frac{h}{\Delta}$ is temporarily assumed to be equal to $6\,E$, the fixed-end moments in each column are equal to the K-value of that column.

These fixed-end moments are balanced in the usual manner until all joints are in equilibrium. The resulting story shears are then compared with the wind shears. If the ratios between the calculated shear and the wind shear in all stories are approximately constant—that is, if the variation does not exceed 15%—final column moments may be obtained with satisfactory accuracy by multiplying the calculated column moments in each story by the ratio of the wind shear to the calculated shear in that story. Final girder moments are obtained by dividing the sum of the column moments at a joint between the girders meeting at that joint in the same ratio as that of the uncorrected girder moments.

In certain structures one may find that the ratios of wind shear to calculated shear in adjacent stories correspond with a variation of 10 or 15%, and yet the variation between these ratios for separated stories is much greater. It is well understood that moments applied in one story of a frame have little effect upon moments in any other stories, except those adjacent to the one under consideration. Accordingly, one need compare only the ratios of wind shear to calculated shear in adjacent stories, and if these ratios do not vary from each other by more than 10 or 15%, the moments may be corrected simply by proportion.

If shear ratios in all adjacent stories change in the same direction by 15%, those for the first and sixth stories will vary from each other by 100 per cent. Nevertheless, approximately correct final moments can be obtained by proportion. The reader can prove this statement for himself in a simple manner. Consider a group of stories cut from a frame in which all columns and girders have the same *K*-values, all stories have equal heights, and the wind shear changes from the top downward by increments of 20% of the shear in the top story. If fixed-end moments equal to the *K*-values of the columns are balanced, it will also be found that successive ratios of wind shear to calculated shear increase uniformly from the top downward by increments of 20 per cent. However, when corrected by proportion, the moments are within 11% of the true moments. It follows that a reasonable correspondence (less than 15% variation) between the ratios of actual shear to calculated shear in adjacent stories of a building frame is the only important criterion for determining when final moments may be obtained by proportion.

The foregoing discussion makes it clear that the method of balancing fixed-end moments equal to the *K*-values of the columns is directly applicable to practically any frame that has a reasonably smooth deflection curve even if this curve does not approach a straight line. An interesting example is that of a set-back building. If the parts of the building above and below the set-back are reasonably regular, it is only necessary that one estimate carefully the relative deflections of the first two stories above and the first two stories below this point, in order to set the relative slopes of the two assumed straight deflection lines. (A method of estimating deflections will be developed in a later section of this paper.) From this point the analysis is unchanged except that fixed-end moments in the upper part of the building are equal to the *K*-values of the columns multiplied by the ratio of the slopes of the top and bottom parts of the building. The fixed-end moments in the lower section of the building are taken as equal to the *K*-values of the columns.

An example of the application of the simplified method in the form suggested herein (balancing fixed-end moments equal to the K-values of the columns) is given in Fig. 4. The frame selected is the lower stories of the Wilson-Maney bent that was analyzed by the slope deflection method in *Bulletin No. 80* of the University of Illinois Engineering Experiment Station. The dimensions of this frame and the K-values of the members are given in Table 1. This structure, being of regular proportions, is well suited to analysis by the simplified method in the form described previously.

A brief explanation of the computations in Fig. 4 seems desirable. The figures enclosed in small boxes at the joints are percentage factors for balancing moments around the joints. The first figure at the top of each row of column moments represents the original fixed-end moment, which is equal to the K-value of the column. There are no fixed-end moments in the girders. The center girders of this symmetrical building are represented as having pins at their mid-points, which are fixed against translation. This represents their true condition and is permissible, provided their K-values are increased 50% when the distribution factors are determined. If this simplification is used, there are no carry-over moments for the center girders. As usual, a single horizontal line indicates that a balancing moment has been recorded immediately above, and two horizontal lines indicate that an entire balancing process has been completed. The final moments, obtained by proportion, are shown in parentheses.

When the ratios of calculated shear to wind shear in each story of the Wilson-Maney bent (Fig. 4), were determined, they were found to correspond within a variation of 11% for adjacent stories. Accordingly, the balanced moments were corrected by proportion, and the final moments will be found to check the true moments as determined by the slope deflection method within a maximum error of 7 per cent. This frame has also been analyzed by the Ross-Morris method and the Fleming Method No. 1, and the reported moments[4] showed maximum errors, respectively, of 15 and 39 per cent. A comparison of the moments obtained from Fig. 4 extended to seven stories, with the exact moments by the slope deflection method, is given in Part (*a*) of Table 2.

INTRODUCTION OF CORRECTION MOMENTS FOR BALANCING SHEARS IN AN IRREGULAR FRAME

If the method of estimating fixed-end moments to be in proportion or equal to the K-values of the columns is used on an irregular frame, one will not find the ratios of wind shear to calculated shear to be alike, even approximately, in all adjacent stories. Since these criterion ratios must be made to correspond, it is necessary to introduce additional fixed-end moments into certain stories to bring these ratios reasonably close together. After estimating the total fixed-end moments required to accomplish this purpose, the fixed-end moment for a given story is divided among the columns in proportion to their K-values. These moments are then re-balanced and the results are added algebraically to the first balanced set of moments. Then, if the

† Slope deflection moments were computed by Ross and Morris and are given in inch-pounds ÷ 10 000.

criterion ratios for adjacent stories correspond within the desired limits, final moments are obtained by proportion.

Some difficulty may be found in estimating correctly the total fixed-end moments to apply in neighboring stories in order to make the criterion ratios correspond. In selecting the value of the moment to be applied in a given story, one must consider the fact that the final balanced moment will be changed by considerably less than the value of the applied fixed-end moment. It is also of importance that a total positive moment applied in a given story will produce a total negative moment in each adjacent story. An estimate of these effects can be made wherever the distribution factors at the joints are known.

An example of the application of this method to an irregular frame is given in Fig. 5. The frame selected is the lower stories of the American Insurance Union Building. Dimensions and K-values of the members for this building are given in Table 1. This structure was chosen since it has been analyzed previously by three methods, one of which was the exact slope deflection method by Ross and Morris.[4] The fixed-end moments selected for the columns in Fig. 5 are twice the Column K-values. These moments were used in order to increase the accuracy of the final moments without making necessary the use of three-place balancing moments. Since final moments are obtained by proportion, it is permissible to multiply all fixed-end moments by any factor desired.

In order to isolate the lower eight stories, assume the moments coming to these joints to be the same from above and below. Do not transfer the carry-over moment across the girder. These approximations make the moments calculated for the eighth story valueless. The final moments in Fig. 5—in inch-pounds, divided by 100 000—are shown in parenthesis. The reader will note the correction moments that are introduced into Story 2.

The first set of balanced moments for the American Insurance Union Building, (Fig. 5) was used to calculate the story shears, and from these shears the ratios of wind shear to calculated shear in each story were determined. These criterion ratios seemed satisfactory except for the low ratio existing in the first story above the mezzanine, which is called the second story in this building. Accordingly, a total fixed-end moment of —160 was divided among the columns of this story in proportion to their K-values and re-balanced. These fixed-end correction moments are the second figures below the first pair of horizontal lines in each column of moments. The value of —160 was chosen after careful inspection as being the smallest total moment that could be applied in this story and still increase the criterion ratio for this story up to approximately the values found in the adjacent stories. The final results justified the selection of this fixed-end moment although either a slightly larger or a slightly smaller moment would have proved to be nearly as satisfactory.

The final criterion ratios for adjacent stories vary from each other by a maximum of 21% and yet the largest error found in a final moment is 12%, which occurs in one of the smaller moments. It is of interest in this connection that the maximum error found by Ross and Morris was 48% by their

of Balancing Moments Equal to Twice the *K*-Values of the Columns in Story 2.

own method and 100% by the Fleming Method No. 1. A comparison of the moments obtained from Fig. 5 with the exact moments by the slope-deflection method is given in Part (*b*) of Table 2.

It is important that the reader realize the practical limitations that should be placed upon this method of analysis, in order that he may understand the field of use for the second method which will be described later. The desire of the writer has been to reduce wind stress analysis to the simple process of balancing one set of fixed-end moments and to eliminate the need for balancing shears with the corresponding introduction of a second, third, and fourth set of fixed-end moments which must be balanced in their turn. The foregoing method of analysis is ideal, wherever the frame deflects into a reasonably smooth curve. For such a structure, the analysis is completed by balancing a single set of fixed-end moments and then by correcting the balanced moments by proportion. Even if there is a considerable irregularity in one or two stories, the method is still advantageous since proper correction moments can be introduced into these stories, re-balanced with small effort, and the moments corrected by proportion as for a regular frame. However, if more than two neighboring stories of the frame are highly irregular, it becomes rather difficult to estimate the proper fixed-end correction moments. In fact, one may err to such an extent in selecting these moments that, after re-balancing, the shear ratios for adjacent stories still do not correspond within the desired range of variation, and it becomes necessary to introduce a second set of correction moments. Naturally, such mistakes are most likely to occur in an analysis performed by one who is unfamiliar with the method.

After making use of this method of balancing fixed-end moments in proportion to the K-values of the columns, the reader will find that its field of major importance is in the analysis of those frames for which an inspection of the arrangement of the members and of their K-values indicates that correction moments probably will be required in one or two stories only. If this inspection indicates that correction moments will be required in a large number of stories, it seems desirable to make a closer estimate of the true relative deflections, in order that the introduction of correction moments may be avoided.

WIND STRESSES IN TALL BUILDING FRAMES OF IRREGULAR PROPORTIONS

In the method of analysis just presented, the story deflections of the frame are assumed to be in proportion to the story heights. The analysis of an irregular frame by this system is complicated subsequently by the need for introducing correction moments into one or more stories of the frame. A method of estimating the true story deflections would seem to offer an advantage since the need for the introduction of correction moments might be eliminated in this manner. In fact, final moments can be obtained within an error of about 6% if the side deflections of each story can be estimated within a variation of 10 per cent. The following method of computing deflections has been found to give approximately this accuracy in all except highly irregular frames. As a maximum error of even 10 or 12% in the wind moments would not be objectionable ordinarily, this method may be used in practical design even for extremely irregular structures. Clearly, this system of estimating deflections may be combined with the conception of producing equal criterion ratios for all stories, by the introduction of correction moments into certain stories, to give a method for determining wind moments within any desired degree of precision.

Since the lateral deflections of a building under wind load are dependent upon the properties of all the columns and all the girders, it seems reasonable that the deflections might be estimated with considerable accuracy by considering the deflections of a single combined column restrained by single girders at each floor level. The K-value of the combined column for each story is taken as the summation of the K-values of all columns in that story, or ΣK_c. The combined girder at each floor level has a K-value equal to twice the sum of the K-values of all girders at that floor, or $2 \Sigma K_g$. The factor, 2, is required because each girder is effective in resisting the moments at two joints. The problem is now reduced to estimating the lateral deflections of this single column with single restraining girders at each floor level.

It is necessary, first, to consider the relation between moment, deflection, and joint rotation in a single story. The lateral deflection of the combined column may be looked upon as made up of two parts: (1) The angle change at the far end times the story height; and (2) the deflection at the near end from a tangent drawn at the far end. However, considering the deflection as divided at the mid-height, as shown in Fig. 6, it becomes clear that,

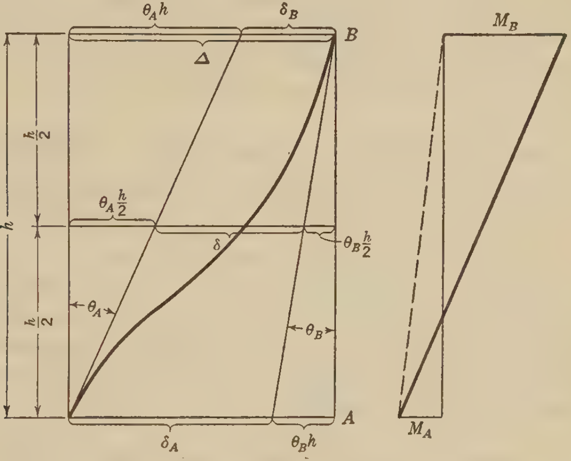

FIG. 6.—COLUMN DEFLECTION.

$$\Delta = \frac{\theta_A + \theta_B}{2} h + \frac{\delta_A + \delta_B}{2} = \theta_{\text{avg}} h + \delta$$

but δ is the average of the deflections at the two ends measured from tangents drawn at the far ends. Hence, δ is readily computed by area moments; thus,

$$\delta = \frac{1}{2EI}\left(\frac{M_A h^2}{6} + \frac{M_B h^2}{6}\right) = \frac{(M_A + M_B) h}{12 EK}$$

The sum of M_A and M_B for the combined column is equal to the total moment, M_t, in the story, which is equal to the shear times the story height, and the K-value of the combined column is ΣK_c. Hence, $\delta = \dfrac{M_t h}{12 E \Sigma K_c}$, and,

$$\Delta = \theta_{avg}\, h + \frac{M_t h}{12 E \Sigma K_c} \quad \dots\dots\dots\dots\dots\dots (4)$$

Equation (4) can also be derived from the slope-deflection equations.

The second term of the expression for Δ is unaffected by the division of M_t into M_A and M_B. However, the first term, which involves the individual values of θ, is dependent upon the division of the total moment between the top and the bottom of the column. When the structure is quite regular, it is sufficiently accurate to assume that $M_A = M_B = \dfrac{M_t}{2}$. In an analysis of the Wilson and Maney bent this assumption was made, and the computed wind moments checked the true moments within a maximum error of 2 per cent. Nevertheless, since the use of fixed-end moments equal to the K-values of the columns is sufficiently accurate for a frame of reasonable regularity, a better approximation of the true division of the total moment between the two ends of the combined column seems desirable. At least, the refinement suggested subsequently will prove advantageous when the stiffness ratios between girders and columns at the two ends of a combined column vary from each other by more than 50 per cent.

The "stiffness ratio of girders to columns" can be defined as:

$$r = \frac{2\,\Sigma K_g \text{ of the girders between Stories } A \text{ and } B}{\Sigma K_c \text{ of the columns in Story } A + \Sigma K_c \text{ in Story } B}$$

This ratio will be called the r-ratio for any floor level.

Let $n_{top} = 2\, r_{top} + r_{bottom}$ and $n_{bottom} = 2\, r_{bottom} + r_{top}$. By checking the moments in several building frames, it has been found that the total column moments at the top and bottom of a story are to each other approximately as the n-values at the top and the bottom of the story. Accordingly, the total column moment is divided as follows:

$$M_{top} = M_t \frac{n_{top}}{n_{top} + n_{bottom}}, \text{ and } M_{bottom} = M_t \frac{n_{bottom}}{n_{top} + n_{bottom}}$$

Note that the n-value at the top of a basement column is ∞ and that the n-value at the bottom is $2\,\infty$. Hence, the total column moment would be divided in the ratio of 67% to the bottom and 33% to the top. This naturally assumes a fixed base at the bottom of the basement column. Economy usually requires that the moments at the top and the bottom of the basement columns correspond more closely than 2 to 1, and, accordingly, it seems desirable to place an upper limit of 60% on the division of moment.

By adding the total column moments above and below any floor level, the moment in the girder, M_g, is obtained. Since the K-value of the combined girder is known, its angle change or the joint rotation can be computed by area moments if the assumption is made that there is a point of contra-flexure at its mid-point. For this case, from Fig. 7,

$$\theta = \frac{M_g l}{6\,EI} = \frac{M_g}{6\,E\,2\Sigma K_g} = \frac{M_g}{12\,E\Sigma K_g} \qquad\qquad (5)$$

When all the θ-values have been determined, it is possible to compute the values of Δ for each story from the known relation,

$$\Delta = \theta_{\text{avg}}\,h + \frac{M_t h}{12\,E\,\Sigma K_c} \qquad\qquad (6)$$

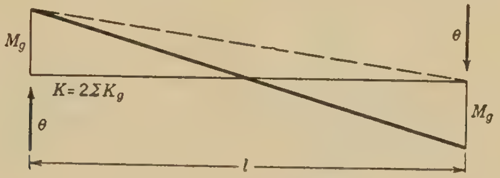

FIG. 7.—JOINT ROTATION.

The fixed-end moments in the individual columns caused by the side lurch are calculated from Equation (3), in which, K is successively the stiffness ratio for each individual column. There are no fixed-end moments in the girders. The fixed-end moments in the columns are balanced in the usual manner around the joints to obtain the first set of balanced moments.

When the balanced moments have been obtained, the column shears are calculated and added together. The total shear should equal the wind shear, and the difference is a measure of the error in the uncorrected moments. If these shears are within 10% of the true shears, the final moments can certainly be obtained with sufficient accuracy by proportion (maximum errors of about 6%). The final column moments are proportioned so as to make the calculated shears check the wind shears. The final girder moments are obtained by dividing the sum of the final column moments at a joint between the girders in the same ratio as that of the uncorrected girder moments.

If the first computed shears in certain stories vary from the true wind shears by more than 10 or 15%, the designer must use his judgment as to whether the foregoing method of correcting the moments by proportion will be sufficiently accurate to meet his requirements or whether it will be necessary to introduce correction moments into certain stories, as has been described in a preceding section. It seems improbable that the important moments obtained by proportion would ever be in error more than 10 or 12% when the calculated shears checked the true shears within 20 per cent. If continued experience with the method justifies this assumption, the need for introducing a set of correction moments probably will never arise.

The lower eight stories of the American Insurance Union Building were analyzed by the simplified method making use of the n-values as explained. The computations of the fixed-end moments for the lower eight stories are given in Table 3. The fixed-end moments are balanced, criterion ratios are computed, and final moments are determined in Fig. 8. Final moments are shown in parenthesis and are in units of inch-pounds divided by 100 000. These final moments are compared with those determined by the slope deflection

method in Part (*c*) of Table 2. The maximum variation in moment found by the simplified method when applied in this form was 9% when checked against the moments obtained by the slope deflection method. Note that this accuracy was obtained from balanced moments that had been carried out to two places only. It will be recalled that this same building was analyzed by the first form of the simplified method, in which fixed-end moments in proportion to the *K*-values of the columns are balanced, and that the maximum error in the final moments was 12 per cent. It will also be recalled that correction moments were introduced into one story in this analysis. Accordingly, the second form of the simplified method, which involves a preliminary estimate of story deflections, was more satisfactory for the analysis of this structure and will usually be found advantageous for the analysis of such irregular frames.

The time consumed by the two variations of the simplified method was not very different for this frame. In the first analysis, time was required for the introduction of correction moments into the frame, while in the second analysis about an equal amount of time was required to make the preliminary estimate of deflections. In either case, there is an appreciable saving over the time consumed by the general method of successive corrections, although the saving is not as important as was found for the more regular frame.

FIG. 8.—BALANCING FIXED-END MOMENTS OBTAINED FROM THE DEFLECTIONS ESTIMATED IN TABLE 3, AMERICAN INSURANCE UNION BUILDING.

Effect of Column Deformation

Since the windward columns lengthen while the leeward columns shorten under wind load, there are fixed-end moments produced in the girders by this effect. The obvious procedure is to determine the direct stress deformations in the columns after having determined the wind moments. From these deformations the fixed-end girder moments are computed and balanced. These balanced moments must be made a part of the original analysis, and since they produce story shears, the criterion ratios will be changed. The final moments are these balanced moments plus the wind moments obtained by proportion using the new criterion ratios.

Naturally the direct stresses, if re-computed, would be found slightly changed, but a further revision of moments would seem to be unwarranted. In fact, it is only in the tower structure that column deformation becomes of importance in wind stress calculations. The writer has estimated the possible effect of column deformation in a discussion[7a] of the Second Progress Report of Sub-Committee No. 31, Committee on Steel of the Structural Division, on Wind-Bracing.

The effect of column deformation can be included directly in a second analysis whenever a revision of the sizes of the members makes a second analysis necessary. The approximate direct stresses in the columns are then known, and the fixed-end girder moments may be introduced and balanced along with the fixed-end column moments. Note, however, that the column moments must have been obtained from absolute rather than relative story deflections. Otherwise, the effect of column deformation would be either exaggerated or minimized when final moments are obtained by proportion.

The Open-Web or Vierendeel Truss

This structure is rather unusual, but does occur where clear openings are required in building design and has been used as a bridge structure, largely in Europe. Its analysis for fixed loads may be made by the simplified method either in the form of balancing fixed-end moments in proportion to the K-values of the members or by balancing fixed-end moments obtained from the estimated panel deflections.

The analysis of the open-web truss by balancing fixed-end moments equal to the K-values of the members is almost identical to the similar process for a building frame. In this structure the fixed-end moments occur only in the horizontal members or chords, provided the effect of direct stress deformation is to be neglected, as is usual. Depending upon the number of panels in the truss, it may or may not be necessary to introduce correction moments into the various panels before adjusting moments by proportion. The criterion ratios for adjacent panels must be made to correspond within about twice the maximum variation to be expected between the calculated moments and the true moments. In other words, if a 5 or 6% error is permissible in the final moments, a 10% variation may be allowed between the criterion ratios for adjacent panels.

[7a] *Proceedings*, Am. Soc. C. E., May, 1932, p. 956.

It will be an obvious improvement to assume that a parabolic or circular deflection curve exists rather than one of triangular shape. The latter is assumed automatically to be the deflection curve if all fixed-end moments are taken as equal to the K-values of the chords. A parabola will serve as well as any other standard curve, and its properties are most readily determined. From the relative assumed deflections of the panel points, one determines the ratios for the various panels by which the K-values of the chords must be multiplied to obtain the original fixed-end moments. The process is simple enough to make a detailed explanation seem unnecessary.

USE OF THE SIMPLIFIED METHOD OF WIND STRESS ANALYSIS IN THE DESIGN OF A TALL BUILDING FRAME

The simplified method of wind stress analysis is convenient for use in the design of a tall building frame. Any statically determinate method of analysis with which the designer is familiar may be used in estimating the wind moments and direct stresses to be used in a preliminary design of the structure. The statically determinate method of analysis must be supplemented by the designer's judgment wherever there are extreme irregularities in the frame. When the sizes of the members have been determined for the most serious combination of dead load, live load, and wind, the simplified method of analysis should be used to determine the true wind moments in this frame.

Slight revisions of the proportions of the frame will probably be necessary to care for the new distribution of wind moments. If the preliminary design was made by an experienced designer, these changes will usually be so unimportant that a new analysis will not be required. Where considerable change is found necessary in the sizes of a few members, it may be desirable to re-distribute the moments about the joints into which these members frame. If radical changes must be made in the sizes of a number of members, it will be necessary to repeat the analysis. However, in this second analysis, the designer has at his command an almost exact knowledge of the story deflections (obtainable from the data of the first analysis), and, therefore, the labor of the second analysis is slightly reduced.

This outline of design procedure makes it perfectly clear that the experienced designer has a real advantage over the beginner in the use of this method. The design of any indeterminate structure should be simplified by a previous knowledge of correct proportions. Any method of design in which preliminary proportions are set essentially by rule of thumb does not take full advantage of the reduction of effort that experience should offer.

Naturally, the question of economy enters into the problem of establishing the proportions of the structure. Minimum wind moments will occur when points of contra-flexure exist at the centers of the members, and the smallest total direct stresses in the columns occur when the direct stresses in the interior columns are zero. However, a wind stress of from 25 to 50% of the dead load and live load stress in a member is usually allowed without requiring an increase in the size of the member. Accordingly, it is not necessarily true that there will be an important economy obtained by forcing the points of contra-flexure to the centers of the members or by proportioning the structure so that there will be zero direct stresses in the interior columns. In fact, the opposite may readily be true.

Near a point of extreme irregularity in the structure, the designer should study the matter of proportions carefully. For instance, when the lower story columns are fixed at their bases, it is frequently considered desirable to use heavy girders at the level of the first floor to force the points of contra-flexure in the lower story columns down near their mid-height. The importance of this arrangement increases with increase in the height of the building. However, one should realize that a heavy girder at the first floor will also require a reasonably heavy girder at the second floor, neither of which can be stressed up to its allowable stress. This heavy second floor girder is required in order to keep the points of contra-flexure in the second-story columns near their mid-height. The question arises as to whether or not it is more economical to place excess material in these first and second-floor girders rather than to increase the sizes of the first-story columns to care for heavy wind moments. This example is typical of the kind of problem that the designer must investigate around each point of extreme irregularity in the frame. A knowledge of the simplified method is extremely valuable in this connection.

Conclusion

This paper has been limited to a presentation of a general system of analysis for stresses in continuous frames that undergo joint translations but in which the loading is fixed. An analysis for the effect of moving loads is an entirely different matter and is not considered. The reader will probably see such an application in the calculation of the maximum stresses for a Vierendeel bridge truss. Since the value of this method of analysis is dependent upon its usefulness to the designer, the writer has indicated briefly its application to the design of the most important structure in this field—the tall building frame. A discussion of the proper proportions of building frames was intentionally omitted from the paper, although a study of the relative economy of frames having various deflection curves would be both interesting and valuable.

Since certain examples mentioned in this paper have been solved to within a range of error of 2 or 3%, it is feared that the reader may draw the conclusion that this precision is put forward as desirable. Such precision is clearly wasted because even the physical properties of materials are not known to this degree of exactness. On the other hand, it seems to the writer that the entire attitude of the designer must be demoralized by the knowledge that his tool for wind-stress analysis may be in error by from 50 to 100 per cent. Careless design would be the natural result. Any tool for wind stress analysis, such as the simplified method, by which the designer can compute the wind stresses to conform to a predetermined standard of accuracy, should tend to increase his confidence in the value of his calculations and improve the quality of his design work. Compared with the importance of this result, the value of a discussion as to whether the standard of accuracy in wind stress analysis should be set at a maximum error of 5, 10, or 20% seems trivial.

DISCUSSION

FRANCIS P. WITMER,[8] M. AM. SOC. C. E. (by letter). — Apparently, by making a reasonably close preliminary estimate of the horizontally deflected positions of the various joints, it is expected that the effect of "side-sway" may be found more expeditiously by Professor Grinter's method than by the process of repeatedly equalizing shears in each story, as described in the Second Progress Report of Sub-Committee No. 31, Committee on Steel, of the Structural Division, on Wind-Bracing in Steel Buildings.[9]

Apparently, the effect of vertical translation of joints, due to column distortions under direct wind stress, may be found either at the same time with the effect of horizontal displacements by making this consideration a part of the original analysis, or it may be included in a second analysis covering only these vertical translations.

If the analysis of the frame is first made by the method described in the progress report previously mentioned, neglecting column axial distortions, the horizontal movements will be fully cared for. A second analysis by the Cross method may then be performed for the vertical distortions only, considering these as producing secondary moments, and following Professor Grinter's method for obtaining the starting fixed-end moments in cross-girders. Should this second analysis result in new column axial distortions of sufficient size to justify it, a third analysis, and even a fourth, may be necessary to determine with sufficient accuracy the moments resulting from vertical displacements. The combination of these secondary moments (and, if required, those also of higher orders) with moments from the original analysis will produce the final moments in the frame.

Professor Grinter describes a solution of secondary stresses in a truss based upon his method, using a Williot diagram to obtain the translations of joints from which starting fixed-end moments are found. The writer described[10] a similar method in 1932.

ELMER K. TIMBY,[11] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper Professor Grinter treats wind stresses in building frames of both regular and irregular proportions. To develop the methods presented, certain assumptions were made, and the purpose of this discussion is to inquire as to whether variations from these primary assumptions materially affect the reliability of the results obtained when using the simplified method.

The first assumption made in the treatment of regular symmetrical frames is that the deflections in all stories are in proportion to the story heights, or, mathematically, that $\frac{\Delta}{h}$ is a constant.

In the development of the method for estimating deflections of irregular building frames Professor Grinter assumes that the total moment in any column other than the basement column is equally divided between the two ends. This is equivalent to assuming a point of contra-flexure at mid-story height. For the basement column, the end moments are assumed to be 40% of the total at the top and 60% of the total at the bottom, which slightly raises the point of contra-flexure.

[10] *Engineering News-Record*, January 28, 1932.

[11] Instr., Eng., School of Eng., Princeton Univ., Princeton, N. J.

It is stated in the paper that a wind bent of ideal proportions should have identical columns in each story, and stories of constant height; and, further, that the K-values of the columns and girders should increase from the top downward in direct proportion to the story shears.

In 1930, Messrs. H. W. Coultas and V. H. Lawton, using a Beggs deformeter apparatus, conducted a most complete experimental analysis of a building frame.[12] The writer has calculated by the area-moment method the deflections of this structure, using the moments determined by the experimental analysis.

It will be seen from Fig. 9(a) that the frame is six stories high, totaling 79 ft to the roof beams, and that its width of 51 ft is equally divided into two bays, making it symmetrical about the center column, $C(2)$. The wind load was assumed to have an intensity of W lb per unit of area above the point, A, shown slightly above the center of the left column, and three-fourths of W lb below Point A. The shaded areas on Fig. 9(a) represent the moments of inertia of the members. It will be observed that the values for the columns increase from top to bottom quite uniformly; that the story heights are nearly equal, having a maximum variation of 1 ft; and, further, that the frame is regular and symmetrical. Therefore, this frame selected at random satisfies to a remarkable degree the conditions stipulated by Professor Grinter as defining an ideal frame.

Fig. 9(b) is a shaded moment diagram for the center column, $C(2)$. It will be observed that the columns in the top three stories have no point of zero moment and, therefore, no point of contra-flexure, and that the second-story column has the point of contra-flexure extremely close to the lower end. Both these observations appear to be at variance with the assumptions made by Professor Grinter.

Fig. 9(c) gives the deflection of the center column, $C(2)$, from a tangent at the base. It will be seen that the deflections in the stories are not proportional to the story heights. If this were true, the deflection curve would be a straight line from top to bottom.

The variation of the slope of the deflection curve may be observed in Fig. 9(d). These values of $\frac{\Delta}{h}$, which are assumed to be constant in Professor Grinter's paper, change from $+136$ to -4. These values were computed, assuming the tangent at the base to be vertical.

Any method which reduces the amount of time or labor required for the solution of a problem, and which, at the same time, yields a high degree of accuracy, is to be highly commended. The writer would like to inquire, however, whether or not these apparently radical differences between assumptions and conditions materially affect the accuracy obtainable with the author's simplified method.

(d) Value of $\frac{\Delta}{h}$ Multiplied by 100 000 for Column C_2

FIG. 9.—FRAME ANALYZED BY MESSRS. H. W. COULTAS AND V. H. LAWTON.

The writer felt, before making this investigation, that the assumption, $\frac{\Delta}{h}$ = a constant, might not be reliable for frames of great height, because of the important effect of column strains. He was surprised, however, to find that the assumption does not appear to be valid for some simple regular frames of low height. A discussion of this particular point by Professor Grinter would be appreciated.

N. A. RICHARDS,[13] M. AM. SOC. C. E. (by letter).—In this paper Professor Grinter offers a method for the analysis of continuous frames in which joint displacements occur. After illustrating the applicability of this method to other frames, he shows how it may be used in the design of high building frames subject to wind. Like other methods of analysis, it presupposes the existence of a design to analyze, and this design must be prepared by some method wholly distinct from this method of analysis.

In buildings of moderate height and dimensions, in which the bracing is not the prime feature of the design, it might often happen that this method would prove useful in a check to determine whether the ordinary members in the building frame would be overstressed from an assumed wind. However, if the building frame presents a major wind problem, due to its height or narrowness, it seems to the writer that it is approaching the design in a backhanded way to create it by some approximate method, and then analyze and revise it by a method such as is suggested.

---

[13] Vice-Pres., Purdy & Henderson Co., New York, N. Y.

In the design of structural members generally, such as girders, beams, and columns, subject to dead and live loads, the designer proceeds in a direct manner to the selection of members sufficient for the conditions of loading, bending, and shear, and without the necessity of a review of some other method to determine whether the members will act as designed.

In their Third Progress Report the members of Sub-Committee No. 31, Committee on Steel, of the Structural Division, on Wind-Bracing in Steel Buildings indicate[14] their belief that they have suggested a method of approach to wind-bracing design, which enables the designer to proceed in as direct a manner to the selection of the members of such a frame, and with no more necessity for review by another analytical method.

It is not the purpose of this comment to criticize the merits of Professor Grinter's method, but rather to bring out the fact that it is of value principally as a method of analysis, and not as a tool of design.

JOHN B. LETHERBURY,[15] JUN. AM. SOC. C. E. (by letter).—The author's method of determining wind moments and deflections supplies a rapid means of solving an otherwise laborious problem. The writer was particularly interested in the conception of a combined girder and column replacing the wind bent, and he desired to experiment with the method on a frame with which he is familiar.

The frame shown in Fig. 10(a) was chosen originally for use in comparing a statically determinate method with the method of moment and shear adjustment suggested[16] by Sub-Committee No. 31, Committee on Steel, of the Structural Division, on Wind-Bracing in Steel Buildings. The only requirements were, that it should be somewhat irregular, and that its stiffness should increase from top to bottom. Moments were obtained with an accuracy of about 10% by three cycles of distribution.

The deflections of Columns A and D were calculated by the method suggested by the Sub-Committee[16] and are shown in Fig. 10(b). The deflections of the combined column and girder calculated by Professor Grinter's method are also shown. All three of the curves approximate a straight line. The combined column and girder deflects but little more than either of the columns, the maximum difference being about 7 per cent. This would seem to indicate that the fixed-end moments could be considered as proportional to the stiffness of the columns.

[14] *Proceedings*, Am. Soc. C. E., December, 1933, p. 1601.

[15] Instr., Civ. Eng., Drexel Inst., Philadelphia, Pa.

[16] Second Progress Report of Sub-Committee No. 31, Committee on Steel, of the Structural Division, on Wind-Bracing in Steel Buildings, *Proceedings*, Am. Soc. C. E., February, 1932, p. 213.

A slight break occurs in the deflection curves at the top of the fifth story, indicating that the effect of the set-back occurs at that point. An increase in uniform wind loading on the upper stories would cause a similar break in the curve which would then approximate two straight lines joined by a curved line. A much higher frame might show a deflection curve more nearly approximating a flat parabola than a straight line, but as Professor Grinter has pointed out, the story deflections would be sufficiently uniform to warrant the assumption of fixed-end moments proportional to the K-values of the columns.

(a) DIMENSIONS OF FRAME

(b) DEFLECTION CURVES

FIG. 10.

In Fig. 11, the moments, in foot-kips, are shown for the set-back portion of the frame. The moment in each case faces the member to which it is applied. Values in parenthesis—thus, (10.00)—are by the Grinter method; those marked by an asterisk—thus, 10.00*—are by the Bowman method; and the remainder are by three cycles of moment and shear distribution. Fixed-end moments were calculated from the story deflections and carried through two cycles of distribution, which brought the final moments into close agreement with those obtained by three cycles of moment and shear distribution. The criterion ratio for the sixth story was 1.05.

The statically determinate method[17] used is shown for comparison. It was devised by H. L. Bowman, M. Am. Soc. C. E. It has been found to give reasonably good results on a number of frames. This is due largely to the excellent shear division between columns obtained by an empirical equation based on the study of several bents which were solved by more exact methods. The other two assumptions necessary for solution are those locating points of contra-flexure in the columns and girders. The writer mentions this method because of its good results and its flexibility in application to design. Table 4 gives a comparison of the column shears, in kips, in the frame shown.

FIG. 12.—COMPARISON OF MOMENTS IN THE TWO LOWER STORIES.

In Fig. 12, the comparison for the two lower stories is given, the units and symbols being the same as those in Fig. 11. In this, the fixed-end moments calculated by the simplified method were carried through four cycles to a criterion ratio of 0.96. The statically determinate method is within 20% of agreement.

The writer believes that the simplified method reduces the labor of wind-stress analysis and the calculations of frame deflections to a minimum consistent with reasonable accuracy. The conception of a combined column and girder may be developed into a yardstick for the measurement of tower deflection and vibration. The natural period of the frame could be calculated from its mass and the deflections of the combined column and girder, assuming harmonic motion and some possible gust forces. The amplitudes and frequencies thus obtained would be in excess of the actual ones in the finished building. It seems logical to attack the problem by means of Professor Grinter's conception.

FREDERICK MARTIN WEISS,[18] JUN. AM. SOC. C. E. (by letter).—The author is to be commended for his efforts to simplify a solution to one of the most complex problems arising in structural engineering. Although the system of analysis presented may deserve considerable space in college textbooks and discussion in academic circles, it is scarcely likely to prove to be the "short-cut" long awaited by practising structural engineers. Conclusions as to its practical worth must not be drawn from the sample calculations relating to the lower parts of the Wilson and Maney bent and the American Insurance Union Building bent.

---

[18] Passaic, N. J. Mr. Weiss resigned from the Society on December 28, 1933.

In the first place, nothing but the simplest method of wind-stress analysis can possibly be applied to a tall building comprising a vast number of members requiring such attention. The three sample calculations presented by Professor Grinter, contain 14, 43, and 21 members, respectively, and from these an estimate may be obtained of the time and labor required per member. Then, when one is informed that such a skyscraper as the 56-story Irving Trust Company Building, in New York City, contains approximately 6 200 members in the wind-resisting part of the frame, it becomes evident that, because of the limited time allowed a structural engineer for the complete design of a steel-framed building, "exact" or "semi-exact" analyses must be abandoned and resort made to less tedious and laborious methods. This is not a plea for the adoption of quick and inaccurate wind-stress calculations, but merely a revelation of the magnitude of the task confronting designers of high buildings.

In the second place, Professor Grinter seems to have overlooked one of the peculiar characteristics of modern tall buildings. Unfortunately, these characteristics do not occur in the Wilson and Maney bent, or in the American Insurance Union Building bent, which were necessarily chosen because slope-

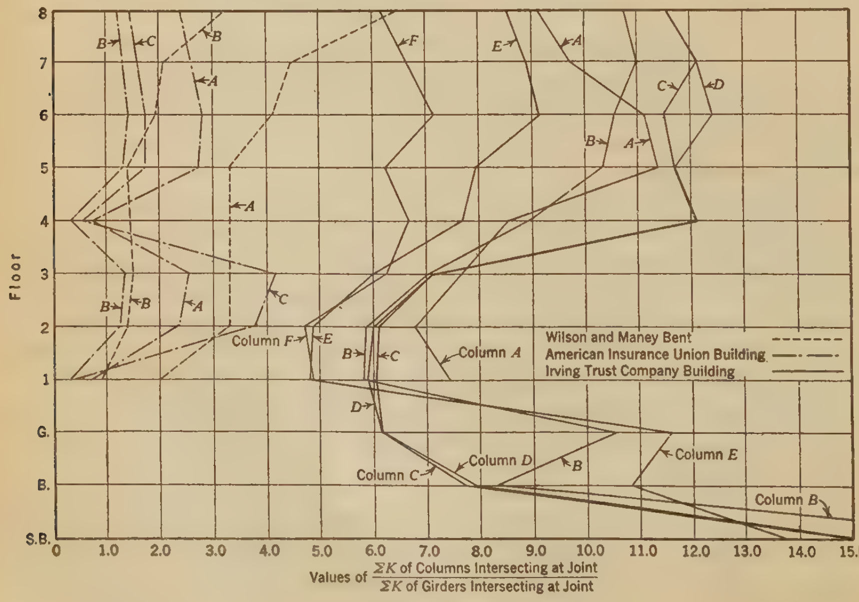

FIG. 13

deflection analyses were available for them. In general, it will be found that in tall buildings the stiffness ratios of the lower-story columns will be many times the stiffness ratios of the girders connected to them. In applying the simplified method of successive corrections to the analyses of such building bents, the convergence of approximations will be very slow because, upon balancing any joint, very little of the unbalanced moment will be distributed to the girders. Since the original fixed-end moments of the girders are zero, and since the balancing moments are small and the carry-over moments are even smaller, it is evident that a great many approximations must be performed before the final balanced moments of the girders at any joint are sufficiently large to equal the sum of the column moments at the same joint.

A rough estimate of the rapidity with which convergence of the approximations may be expected can be obtained from the quotient of the sum of the stiffness ratios of the columns intersecting at a joint divided by the sum of the stiffness ratios of the girders intersecting at the same joint. The larger these quotients are, the slower will be the rate of convergence. In Fig. 13 values of these factors are plotted for the lower eight floors of the Wilson and Maney bent and for the lower eight floors of the American Insurance Union Building bent, together with values for the lower eleven floors of a bent selected through the tower of the Irving Trust Company Building. The necessary dimensions, in feet, and moments of inertia, in inches⁴, for the Irving Trust Company Building are arranged for reference in Table 5.

* *G* = ground floor; *B* = basement; and *SB* = Sub-basement. † Foundation walls.

It will be noticed in Fig. 13 that the values for the Wilson and Maney bent and for the American Insurance Union Building bent are very much smaller, in general, than the values for the Irving Trust Company Building.

In conclusion, therefore, it may be stated that to attain a desired degree of accuracy, the practical application of this variation of the Cross method may become such a Herculean undertaking as to overshadow completely the task performed by Professors Wilson and Maney in solving sixty simultaneous equations.[19]

Raymond C. Reese,[20] Assoc. M. Am. Soc. C. E. (by letter).—In applying Professor Cross' method of moment distribution and Professor Grinter's simplification, the designer is mainly interested in how quickly he can obtain reasonably accurate results. From the nature of the problem, no "exact" solution can be expected; nor is it necessary.

The work required is dependent upon the speed with which the moment distribution converges; while the accuracy can only be determined by agreement with other recognized methods of attack. The speed of convergence, again, depends upon the relative stiffness of the members, particularly the ratio of story-column stiffness to the stiffness of one tier of beams.

Most of the recorded examples are fairly regular frames, as that is the only kind amenable to the so-called "exact" methods that are used as a check. In actual work, however, it is seldom possible to make such simple and regular frames. This is particularly true of reinforced concrete buildings, where the designer has an unlimited choice of sections.

The writer was making a review of the wind stresses in an ordinary fifteen-story reinforced concrete hotel building for another purpose, and it seemed an excellent chance to determine the speed of convergence of the distribution. The remainder of this discussion will be concerned solely with this one phase of the problem.

Fig. 14(*a*) is a diagrammatic elevation of the end bent of this building showing dimensions. The carry-over factors and stiffness ratios for this bent are presented in Table 6. The building is sufficiently high and narrow to make the wind stresses a factor in the design. In the original design Fleming's method was used, of taking points of inflection at mid-girder span and mid-column height, and apportioning column shears on the basis of one-half portion to the exterior columns and a full portion to the interior columns.

The size and shape of many of the members were determined by architectural considerations. The column adjoining the stairs was of long, narrow cross-section, to clear the stair shaft, and was built with three spirals. The depth of spandrels was fixed by the legal height of the window heads. They could not be inverted because of the steam return lines buried in the walls; but were deepened at the ends to afford as much wind resistance as possible. Double reinforcement was used in these beams.

This frame, therefore, is typical of what can be expected in reinforced concrete buildings designed for maximum economy, and meeting the necessary requirements as to space and clearances. The members differ widely in their relative stiffness. In the lower stories the columns are much stiffer than the girders. All these factors operate to slow down the convergence of the moment distribution.

The details of the computations are too lengthy to be reproduced in full. Points *a, b,* and *c* (Fig. 14(*a*)) were selected as typical.

Method 1.—The first attack was made along the lines suggested by Clyde T. Morris,[21] M. Am. Soc. C. E.; that is, the wind moment in a story was apportioned among the columns of that story according to their relative stiffness. No moment was apportioned to the girders. Second, the moments around each joint were balanced, which transferred some of the column moment into the attached beams. Due to their relatively small stiffness ratios, only a small percentage was transferred in any one step, which slowed the convergence. As the third step, the corresponding carry-over quantities were added. This completed one cycle. After all the stories were similarly balanced, a second cycle was started in the same way. Curves 1 to 3, Fig. 14, indicate the rate of convergence for successive cycles by this method. It should be remarked that because of the haunches on the girders, the carry-over factors differ from the customary 0.5 of the prismatic section (see Table

---

[21] *Transactions,* Am. Soc. C. E., Vol. 96 (1932) p. 66.

6). It was found that after twenty-three cycles of operations, the results were still a considerable distance from a final value. After each cycle of operations the resultant moment is plotted against the number of the cycle. The values approach the true values at a decreasing rate, and any estimate as to the probable number of cycles required will fall short unless one can foresee how rapidly the rate of convergence is decreasing.

As the work progressed, attempts were made to forecast the final, probable values, with the idea of eliminating the intermediate steps. Professor Grinter's suggestion of proportioning from the rule:

$$\text{Final moment} = \text{Balanced moment} \times \frac{\text{True shear}}{\text{Calculated shear}}$$

was adopted after each cycle. In Curves 4 and 5 these estimates of the probable final values are recorded as "adjusted." It is to be noted that after a few cycles the estimates are amply close for practical purposes, although rather short of true mathematical agreement.

It would appear, judging from this single, asymmetrical instance, that satisfactory results can be obtained by the application of Professor Grinter's proportion even before the moment distribution has become steadied sufficiently to indicate the final values; but about twelve to fourteen cycles were necessary to make these adjusted moments reasonably close.

Method 2.—The foregoing method is too tedious to permit its application to actual design problems. The mere number of computations, even if they are of the simplest arithmetic, leaves a feeling of doubt. Fortunately, errors tend to work themselves out under repeated distributions; but the method is unduly cumbersome.

The slowness is caused by the taking of only a small amount of the column moment at each joint into the beams at each cycle. If the distribution percentage were larger, the convergence would be more rapid. By beginning with a fairly large value in the girders, considerable preliminary work would be eliminated. Arbitrary values could be assumed, but the results might then tend to converge on these values without their being the true results.

It was decided to start with the values obtained by the ordinary approximate solution. These values were first adjusted because it was impossible to have the same moments in the haunched beams and in the full depth spandrel. Consequently, about 10% was deducted from the approximate moments in each of the haunched spandrels and the corresponding amount was added into the full depth spandrel. This unbalanced the joints, and a rough adjustment of the column moments was made to keep each joint approximately in balance. In some cases, this was impossible. From a common sense viewpoint it was unreasonable to have a greater moment at the top of a column than at the bottom, and yet no other solution would balance the joint. In such cases values were adopted that were as nearly in balance as possible, and, at the same time, as nearly as possible consistent with each other. No careful attempt was made to fill either criterion, as it was felt that a few cycles would adjust the discrepancies.

With these trial values as a start, the same cycle of operations as in Method 1 was gone through seven times. With the girder moments assumed at something like their true values, the convergence is much more rapid. In Curves 6, 7, and 8, are plotted the complete set of computations through seven cycles for the same points, *a*, *b*, and *c*. Here, again, the reproduction of all the detail figures is of no help in visualizing the results. These curves offer a comparison with the previous method.

The approximations of the true final values by the proportion of true shear to calculated shear was applied to the moments in this case, and plotted as Curves 9, 10, and 11, in Fig. 14.

As the values were assumed approximately in balance around each joint and with the columns taking approximately the story moment, the convergence was quick—but not, apparently, on the best, true values. There was a marked tendency to close on the original assumptions. While the adjusted results appear fairly good, the method is mathematically unsound, and the apparent value is based only on a rather fortunate guess in setting up the original assumptions. Actually, the angles between beams and columns are not maintained as true right angles in this method; some relative angle change takes place.

Method 3.—This method followed exactly the author's suggestions for very irregular bents; that is, the *r* and *n*-values for each floor were computed and the total story moment was distributed as suggested. The *K*-values in Table 6 are relative only, and are about one-forty-seventh of the true $\frac{I}{L}$ -values. This does not affect the figures, but simply reduces all values in this ratio. For this reason, it is not possible to plot the various cycles. The results for the three points, *a*, *b*, and *c*, are recorded in Table 7, and the speed with which the figures converge is readily apparent. Six cycles of operations completed the distribution at each point to a precision of about 1 to 2 per cent. The final results at Points *a*, *b*, and *c* are computed by multiplying the values obtained as described, by the ratio of the true shear to the calculated shear; that is, by 7.37 for the fourth-story columns, 8.50 for the fifth-story columns, and the average for the fifth-floor beams.

TABLE 7.—VALUES OF DISTRIBUTED MOMENT AT POINTS *a*, *b*, AND *c* IN FIG. 14(*a*)

Cycle	*A*		*B*		*C*	
	Distributed	Result	Distributed	Result	Distributed	Result
	....	+116.0	......	0	....	+436.0
1.......	−78.5 −39.3	.... − 1.8	−12.2 − 7.4	...... −19.6	−310.0 −155.0	.... − 29.0
2.......	+16.8 + 8.4	.... + 23.4	+ 2.4 + 0.8	...... −16.4	+ 37.3 + 18.7	.... + 27.0
3.......	− 2.0 − 1.0	.... + 20.4	− 0.3 + 0.1	...... −16.6	+ 2.5 + 1.3	.... + 30.8
4.......	− 0.1 − 0.1	.... + 20.2	0.0 − 0.1	...... −16.7	− 3.3 − 1.7	.... + 25.8
5.......	+ 0.2 + 0.1	.... + 20.5	0.0 0.0	...... −16.7	+ 1.2 + 0.6	.... + 27.6
6.......	− 0.1 − 0.05	.... + 20.35	0.0 0.0	...... −16.7	− 0.3 − 0.2	.... + 27.1

The resultant moments were computed, as follows:

$$M_a = -20.35 \times 7.37 = 149.9$$

$$M_b = -16.70 \times 7.93 = 132.5$$

and,

$$M_c = +27.10 \times 7.37 = 199.7$$

At the fifth-floor joints the average value of $E\ \theta$ was equal to 4 960. Table 7 begins with no wind moment in the beams and with column moments obtained from approximate lateral movement as suggested by the author. These final results, only, are plotted as Curves 12, 13, and 14, in Fig. 14.

Method 4.—To check the other methods an analysis was made by slope deflections. The labor involved makes this method prohibitive for the actual design of structures. It is useful, however, as a criterion to measure the degree of approximation of the other methods.

In this case, the solution of the resulting simultaneous equations required considerable care, as the wide differences in the relative stiffnesses caused considerable variation in the coefficients, requiring nine significant figures for a satisfactory degree of precision.

The results at Points *a*, *b*, and *c*, are plotted as constants across all the cycles of Fig. 14 (see Curves 15, 16, and 17.) For comparison with Method 3, the average value of $E\ \theta$ for the fifth-floor joints was 4 920.

Conclusions.—For practical purposes with a bent of three spans of this type, the ordinary assumptions of Fleming's methods give reasonably satisfactory results. They afford the only method for making a preliminary design to use as a basis for more nearly exact elastic computations.

The method of starting with no wind moment in the girders and gradually transferring from the columns into the girders will bring convergence fairly rapidly in simple, symmetrical bents in which the relative stiffnesses of the different members do not vary too much.

When the members vary widely in their relative stiffnesses, the method of starting with no moment in the girders is too slow and tedious a process. In this particular case, twenty-three cycles of operations failed to come very close to the desired results.

By carrying through a few cycles and then proportioning the final values on the basis of the calculated moment in the columns to the true story moment, a number of cycles is saved. If the proportioning is done three or four times, using successive moment values after each cycle, a trend is established which indicates the final value more accurately.

More rapid convergence is obtained by starting with moments as nearly as possible like the final values in the girders. The convergence is rapid, but appears mathematically unsound because there is a marked tendency to converge on the assumed values. If these happen to be nearly correct (and with a little care in selecting them they should be), the results look good, but actually the method does not maintain the right angles between the beams and columns unchanged.

The author's method of approximating the actual story deflections from the relative stiffnesses of the beams and columns combined, and using this deflection to approximate the column moments, gives a much more rapid convergence than the original method of moment distribution. The results seem to be satisfactory. The author stated that some variation in relative stiffness was permissible. In this particular case, the stiffest column is more than 2 700% of the spandrel beam—a wide variation, and yet not more than can be anticipated in concrete structures.

Too many practical considerations are involved to make a high degree of precision necessary or desirable. A method that gives the necessary data for selecting members, rather quickly and sufficiently close for practical purposes, is what is desired.

It appears that one of Fleming's methods is quite close. If a check or more precise determinations is desired, the author's suggested method is by far the simplest. Although the tabulated computations appear rather simple, it should be remembered that they represent only three points, and the detailed computations involve several thousand sets. Approximately 75% of the time of Method 1 was saved in Method 4.

While it is unsound to judge from one or two isolated cases, the results as obtained from this one study are very favorable.

A. Floris,[22] Esq. (by letter).—In this interesting paper the author analyzes the wind stresses in the frames of tall buildings by the aid of the Cross method of balancing fixed-end moments. Furthermore, he states that an exact analysis of these frames requiring the solution of simultaneous equations — as, for instance, the slope deflection method used by Wilson and Maney — is a rather tedious process. For this reason he proposes the application of a less accurate method of moment distribution to the analysis of multiple-story frames subjected to wind pressure.

The present analysis, based as it is on the repeated distribution of the end moments, is to some extent a trial-and-error method. Such indirect methods, however, require considerable time, and their application to practical problems is rather discouraging. Their use can only be justified if direct and speedy methods of analysis are not available.

In the present case this is not necessary, because a direct method[23] has been developed by Professor F. Takabeya which excels in brevity and accuracy all other methods known to the writer. The necessary elastic equations derived by the slope deflection method can be written almost automatically and solved by the principle of iteration. This method of solving simultaneous equations permits the use of the slide-rule and is convenient and simple.

The author's statement regarding the difficulties arising in the analysis of multiple-story frames subjected to an additional translation of the joints, is not quite correct. Such frames are analyzed quite easily by the use of the

---

[22] Civ. Engr., Los Angeles, Calif.

[23] "Methode der Gleichungstabellen zur Berechnung der Rechteckrahman," von Fukehei Takabeya, *Proceedings*, World Eng. Congress, Tokyo, 1929, Vol. VII, Pt. I, p. 277; also, "Rahmentafeln," von Fukehei Takabeya, Berlin, 1930, and "Das Verfahren der Gleichungstabulierung zur Berechnung des durchlaufenden Rahmens mit verschieden hohen senkrechten Stielen," von F. Takabeya, *Der Bauingenieur*, 1933, pp. 92 and 126.

Takabeya method, for instance, with little additional labor, and the calculations are not difficult. Furthermore, the claim that the method of balancing fixed-end moments only involves simple arithmetic is not quite true. In the last analysis any method arranged for practical use requires the application of simple arithmetical processes. For this reason the writer believes that, as an important practical advantage of the method under consideration, this fact is over-emphasized by the author.

Robins Fleming,[24] Esq. (by letter).—Professor Grinter presents a model arrangement of data and calculations. By making a table of story heights and K-values (Table 1) and writing on the diagram of the bent (Fig. 4) at each joint in a rectangle drawn around that joint the percentage factor for adjusting moments, confusion is avoided by the diagram not being cluttered with figures.

To assume that the center girders of a symmetrical bent are hinged at mid-point is an ingenious way of avoiding carry-over moments in these girders.

Professor Grinter's purpose is to present a simplified method of wind analysis. It is not difficult of application, but the designer should understand its limitations. Professor Grinter finds in the lower four stories of the classic Wilson and Maney bent the "criterion ratios" to correspond within a ratio of 11% for adjacent stories. The final or "true" moments are thus found to be within 7% of those obtained by the slope deflection method.

Variations of criterion ratios may be quite different in other cases. M. S. Ketchum, M. Am. Soc. C. E., has offered[25] a problem in which the bending moments of a three-aisle, six-story building are determined by a method outlined by Clyde T. Morris, M. Am. Soc. C. E. Using the K-values given and following the method of Professor Grinter, the criterion ratios vary from 5 to 50 per cent. The ratio in a story is sometimes less and sometimes greater than in the story above. Professor Grinter allows a variation of 15 per cent.

For more than twenty years the writer has sponsored, although he did not originate, the two conventional methods of obtaining wind stresses known as the cantilever and the portal methods. At the same time, he has always insisted that super-tall buildings and those of irregular framing should receive special study. Professor Grinter and other writers call attention to "errors" of 30% and even 100%, in the stresses obtained by the conventional methods. What they mean to say is that they differ by these percentages from those obtained by the slope-deflection method. The correctness of the slope-deflection method is vigorously disputed[26] by J. A. Van den Broek, M. Am. Soc. C. E. David A. Molitor, M. Am. Soc. C. E., who is often quoted, does not regard the basic assumptions of the method as "exact."[27]

[24] Care, American Bridge Co., New York, N. Y.

[25] "Steel Mill Buildings", by M. S. Ketchum, Fifth Edition, 1932, Chapter on "Stresses in Stiff Frames by Moment Distribution".

[26] "Elastic Energy Theory", John Wiley & Sons, Inc., 1931.

[27] *Proceedings*, Am. Soc. C. E., January, 1929, Papers and Discussions, p. 189.

Notwithstanding an occasional assault the consensus of engineering opinion is that it is the most nearly correct of all methods thus far presented. It is not workable, however, for design purposes. The Cross methods, although tedious, are feasible and are valuable for analysis of stresses obtained by other methods. For the purpose of analysis, Professor Grinter's paper is especially valuable.

J. D. GEDO,[28] ESQ. (by letter).—Under the heading, "The Open-Web or Vierendeel Truss," the author states that fixed-end moments in this type of truss occur only in the horizontal members or chords, "provided the effect of direct stress deformation is to be neglected, as is usual."

To neglect the effect of direct stresses is permissible only if they are small in comparison with the moments. No one would neglect the direct stresses in the case of arches; nor is it permissible to do so in the case of Vierendeel trusses.

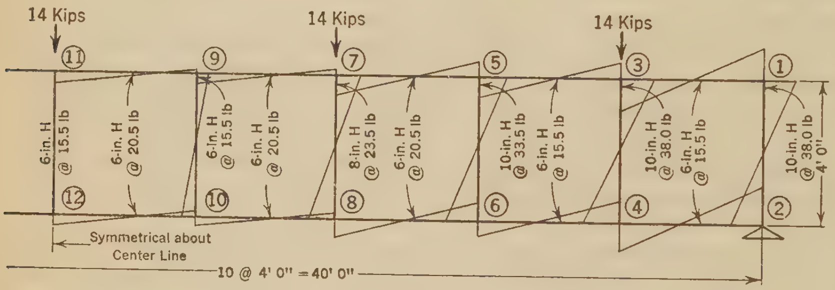

FIG. 15.

The writer solved the example in Fig. 15 by the theorem of least work both by neglecting and considering the effect of direct stresses (in the chords). In Table 8, which gives the results of this study, the subscripts, *A*, *B*, *L*, and *R*, signify "above," "below," "left," and "right," respectively; for instance, M_{8B} is the moment immediately below Joint 8.

[28] Structural Designer, Care, Alexander D. Crosett, Cons. Engr., New York, N. Y.

It is to be noted, in comparing moments in which direct stresses are considered and neglected, that errors as great as 37% (see M_{9L}) can occur.

H. V. Spurr,[29] M. Am. Soc. C. E. (by letter).—The writer agrees with the author (see "Synopsis") that:

> "One of the most difficult problems that the structural engineer must solve is the analysis of stresses in a continuous frame in which joint displacements occur. * * * The calculation of wind moments in tall building frames is such a problem."

He further agrees (see "Use of the Simplified Method of Wind Stress Analysis") that "the experienced designer has a real advantage over the beginner in the use of this method;" or, for that matter, in the use of any method. Furthermore, Professor Grinter is very wise when he states that "the design of any indeterminate structure should be simplified by a previous knowledge of correct proportions." The writer considers it unfortunate that the author did not base his entire paper on these essential facts, since it can be said with equal truth that the anaylsis of an existing structure will be simplified by a previous knowledge of correct proportions.

It can rightly be said that the Cross method has its greatest value as a means of acquiring a visualization of the action of continuous frames, which will assist in developing and perfecting this so-called "previous knowledge" of the engineer, which is so essential to successful design or analysis. Once acquired, this knowledge is so potent as to render the use of the method in detail often both tedious and superfluous. For this reason, the writer must take serious exception to the statement under the heading, "Methods in Common Use," that "to date, the most usable method of wind stress analysis, which also can claim to be more than a rough estimate, is that suggested by Ross and Morris."

It can safely be said that practical design methods are in use in more than one office, that will produce results, the general accuracy of which can not be seriously questioned from the standpoint of analysis. These methods are based on sound mechanics and are used with a visualization of the elastic behavior of continuous frames. Their merit lies in the freedom from arbitrary and incorrect assumptions commonly used in connection with mathematical methods as such. Much confusion and error have occurred in the past from careless assumptions used to make the mathematics apply to a given case.

In the light of "a previous knowledge of correct proportions" how would an experienced engineer initiate his analysis of an existing high building frame? The procedure might be, as follows:

(*a*) Allocate a wind load to each bent that will be tied in later with the design load on the structure.

(*b*) Calculate the horizontal wind shears in the various bents in each story.

---

[29] Chf. Engr., Purdy & Henderson Co., New York, N. Y.

(*c*) Distribute the horizontal shears into the various panels on the basis of beam distortion only, assuming points of inflection at the mid-span points of the beams. Such shears will cause end moments in the beams, which, in turn, will produce extreme fiber stresses in bending inversely proportioned to the span-depth ratios of the beams (based on their clear spans between columns).

(*d*) From the beam moments the column moments and shears may be obtained, on the basis of points of inflection occurring at mid-story points in the columns.

(*e*) The participation of the various columns in the web distortion may be obtained on the basis of these moments and shears. Their relative values may be obtained, and their relation to beam participation in web distortion as well. If the columns participate equally, or if the column participation is small relative to the beam participation, one may proceed to the next step without review.

(*f*) Determine the relative rigidity of the beams from floor to floor based on the assumed moments. If the floors have approximately the same relative rigidity under their respective moments from wind assumed, then the analysis so far is approximately correct, except for the influence of connections, which is a detail not mentioned by the author. A study of the values of relative rigidities between beams and columns and between floors will reveal how the results are to be modified in specific cases. Frequently, no modification is necessary.

Before any such modification is made, however, it is of vital importance to ascertain the possible influence of change in the length of the columns on the entire analysis. If it is found from the analysis at this stage that the assumed shear distribution will induce vertical stresses in the columns, which, in turn, would cause a vertical movement of the joints in such a manner as to throw the various floors more or less out of line, it is useless to make any further refinement in the analysis without taking such action into account.

How this is to be accomplished the author has not seen fit to establish. In many cases, it will be a weary and tedious task if based on conventional methods of correcting and recorrecting for joint displacement in a high irregular frame. For this reason, the writer has paralleled the procedure outlined by the author with one of his own, up to the point of considering column axial deformation. It is hoped that the points of attack outlined may have some useful significance.

In his discussion[30] of the Second Progress Report of Sub-Committee No. 31, Committee on Steel, of the Structural Division, on Wind Bracing, the writer has pointed out the significance of correct proportions in the design and analysis of multi-story frames, and has indicated a simplified use of the Cross method of analysis under certain circumstances. What needs to be emphasized is that the six steps in the analysis outlined in the present discussion will disclose the type of structure with which one has to deal. The degree of its irregularity will be revealed immediately.

---

[30] *Proceedings*, Am. Soc. C. E., August, 1932, p. 1126.

If the structure is regular and well-proportioned the results obtained in the first analysis will be substantially correct, and will be reached in a fraction of the time required by either the general method of successive corrections, or by the author's simplified method. Furthermore, it is important to know as quickly as possible in what manner and do what degree the structure is irregular or unusual. In fact, it is absolutely essential for the engineer to sense these facts, in order to use the simplified method at all, since it is based on: (1) The calculation of the true deflections under the applied loads; (2) producing these deflections by bending in the columns only, with joints fixed against rotation; and (3) balancing the moments in succession at all joints.

It is perfectly true that Steps (2) and (3) are simple of execution, but it is these two steps only which involve the Cross method at all. The real difficulty comes in Step (1) which actually involves the approximate solution of the problem. It is true that under Step (1) the solution obtained may, through lack of insight, be somewhat inaccurate, in which case Steps (2) and (3) will reveal the direction toward which the analysis must move to improve the accuracy. The time consumed in the analysis, however, will depend largely upon the efficiency shown in Step (1), which is all-important.

For this reason the writer believes that progress in the analysis of irregular frames is frequently most rapid through a careful study of deflections or drift produced in the web system by the applied loads, through an intelligent spotting of the positions of the points of contraflexure, and then checking the solution for the condition of minimum deflection in the structure as a whole. This is a common-sense use of the method of least work bearing in mind that the structure will perform under the applied loads in the most rigid manner possible. Frequently, a given structure may have a marked irregularity, but in one respect only, and a reasonable solution is quickly obtained by inspection, or by bracketing the true solution by two analyses somewhat in the same manner that artillery fire is directed.

The author has made a valuable contribution to the art of analysis, but has under-emphasized the degree of art involved in the analysis or design of continuous structures of irregular character. This common error in emphasis is characteristic of nearly all technical papers and discussions on the subject; and it springs from a natural desire of authors and engineers to substitute a definite mathematical procedure for a trained reflection and visualization of the conditions affecting the correct solution.

It should be realized that the actual geometry of deflection is influenced by the clear spans of the members, by the character of the connections, whether angles, split beams, or knee-braces, and, in high towers, that it is largely controlled by the elastic action of the columns under axial stresses. Neither the Cross method nor the slope deflection method are, in themselves alone, suitable instrumentalities for many problems encountered in practice.

JOHANNES SKYTTE,[31] M. AM. SOC. C. E. (by letter).—This paper is of unquestionable value for the analysis of framed structures and particularly for tall buildings acted upon by lateral forces.

In connection with the application of the simplified method for irregular structures, it is of importance to estimate deflections and, for this reason, the following approximate formulas will be introduced: (I) Formula for determining location of point of counterflexure in columns; (II) formula for determining location of point of counterflexure in girders; and (III) formula for determining ratio of girder shears.

FIG. 16.

(I) Formula for Determining Location of Point of Counterflexure in Columns.—For Column *A*, Fig. 16:

$$\frac{M_{\text{top}}}{M_{\text{bottom}}} = \frac{h - y_A}{y_A} = \frac{3h + \alpha\left(\frac{h_1}{2} + h\right) - \beta\,\frac{h'}{2}}{3h + \beta\left(\frac{h'}{2} + h\right) - \alpha\,\frac{h_1}{2}} \qquad \text{.........(7)}$$

in which, $\alpha = \frac{K_A}{K_a}$ and $\beta = \frac{K_A}{K_{a'}}$. Equation (7) will also apply to Column *B*,

---

[31] Hydr. Eng. Designer, City of San Francisco, Hetch Hetchy Dept., San Francisco, Calif.

Fig. 16, when $\alpha = \frac{K_B}{K_a + K_b}$ and $\beta = \frac{K_B}{K_{a'} + K_{b'}}$. Similar results follow for any other interior column.

If a single combined column, restrained by a single girder at each floor level, is considered, then:

$$\frac{M_{\text{top}}}{M_{\text{bottom}}} = \frac{3h + \alpha\left(\frac{h_1}{2} + h\right) - \beta\frac{h'}{2}}{3h + \beta\left(\frac{h'}{2} + h\right) - \alpha\frac{h_1}{2}} \quad \ldots\ldots\ldots\ldots\ldots (8)$$

in which,

$$\alpha = \frac{(K_A + K_B + K_C + \ldots)}{2\,(K_a + K_b + K_c + \ldots)}\text{; and } \beta = \frac{(K_A + K_B + K_C + \ldots)}{2\,(K_{a'} + K_{b'} + K_{c'} + \ldots)}$$

Equation (8) will give closer results than the formula preceding Fig. 7 of the author's paper. It is to be noted that $\alpha = 0$ in the basement story if the columns are fixed at the bottom. Applying Equation (8) to the American Insurance Union Building the results given in Table 9 are obtained (in thousands of foot-pounds).

TABLE 9.—COLUMN MOMENTS BY EQUATION (8)

Story	TOTAL COLUMN MOMENT		Story	TOTAL COLUMN MOMENT	
	Top	Bottom		Top	Bottom
6	1 550	1 550	2	3 030	2 040
5	1 700	1 680	*M*	2 300	2 130
4	1 680	1 650	1	2 810	3 750
3	1 590	2 230	*B*	3 750	4 120

(II) Formula for Determining Location of Point of Counterflexure in Girders.—In Bay *a*, Fig. 16,

$$\frac{l_a - x_a}{x_a} = q\,\frac{1 + r}{3 - r} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which, $r = \frac{5 + q + 2\,\beta}{2\,(q^2 + q + 1) + \alpha\,q^2 + \beta}$; $q = \frac{y_A + (h_1 - y_{A1})}{y_B + (h_1 - y_{B1})}$; $\alpha = \frac{2\,K_a}{K_A + K_{A1}}$; and $\beta = \frac{2\,(K_a + K_b)}{K_B + K_{B1}}$.

Equation (9) will also apply for Bay *b*, Fig. 16, when $q = \frac{y_B + (h_1 - y_{B1})}{y_C + (h_1 - y_{C1})}$; $\alpha = \frac{2\,(K_a + K_b)}{K_B + K_{B1}}$; and $\beta = \frac{2\,(K_b + K_c)}{K_C + K_{C1}}$. Similar results follow for any other interior bay.

(III) Formula for Determining Ratio of Girder Shears.—Let *b* and *c* be two adjacent bays in a bent; then:

$$\frac{X_b}{X_c} = \frac{K_b}{K_c}\,\frac{l_c \pm 6\,\lambda_c}{l_b \pm 6\,\lambda_b} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

In order to determine the sign of λ, it is necessary to consider oneself located at Column C, Fig. 16; then the plus sign applies when the column and the point of counterflexure in the adjoining girders are on opposite sides of the center line of the same girders. The minus sign applies when they are on the same side of the center line. For the sake of illustration apply this rule to the ratio of girder shears in Fig. 16, then: $\dfrac{X_a}{X_b} = \dfrac{K_a}{K_b}\,\dfrac{l_b - 6\,\lambda_b}{l_a - 6\,\lambda_a}$ and $\dfrac{X_b}{X_c} = \dfrac{l_c + 6\,\lambda_c}{l_b + 6\,\lambda_b}$.

JOHN B. WILBUR,[32] ASSOC. M. AM. SOC. C. E. (by letter).—Step (4) of the simplified method of wind stress analysis presented by Professor Grinter, consists of computing the total shear in each story from the balanced moments of Step (3). This is easily done by dividing the sum of the end moments of the columns of a story by the story height, providing one assumes that the wind loads are concentrated at the panel points of a bent. In some cases, however, it might be more correct to assume that the wind load is distributed over the windward column stack of the bent, or partly distributed in this way and partly applied in panel loads.

FIG. 17.—DIMENSIONS, AND STIFFNESS FACTOR, K, OF A BUILDING FRAME (AVERAGE VALUES OF K ARE GIVEN FOR GIRDERS).

That the assumption made with regard to this condition may play an important rôle in determining the computed wind stresses in a bent is illustrated by the following: Consider the moments in the columns and girders of the bent shown in Fig. 17 due to the given distributed wind loads. The moments in Table 10(*a*) were determined by means of a model and deformation apparatus.[33] These results are unusual in two respects: There is no tendency toward symmetry of stress in a symmetrical bent, and several of the members have no points of contraflexure. These conditions can be explained partly by the fact that the model test takes into account (although incorrectly) deflections due to direct stress and shear. The writer did not believe that the effect of these items was sufficiently great to offer complete explanation for the unusual results. A solution was made, therefore, by slope deflection, concentrating the same total wind loads at the panel points, and, to simplify the tedious solution, using average moments of inertia for girders with cover-plates. The results of this solution, which was carried out on a computing machine with considerable accuracy, are given in Table 10(*b*), and show such completely different moment values, that the importance of the manner of loading assumed is apparent at once.

[33] "An Example of the Mechanical Solution of a Statically Indeterminate Structure," by H. W. Coultas and V. H. Lawton, *The Structural Engineer*, October, 1930, p. 344.

In a given building frame, the paths which the wind loads follow in their transfer from exterior walls to wind bents depend on the type of construction used and the ratio of column spacing to story height. For skeleton steel buildings with curtain walls, the assumption that the wind loads are concentrated at the panel points of the bents seems rational to the writer, particularly if the building is tall, or if the ratio of column spacing to story height is large. The possible importance of this assumption in its effects on the computed stresses, however, should not be overlooked.

L. E. GRINTER,[34] ASSOC. M. AM. SOC. C. E. (by letter).—The constructive nature of the criticism apparent in nearly all the discussions of this paper is appreciated. The writer wishes particularly to thank Messrs. Letherbury and Reese for their carefully prepared discussions showing the application of the simplified method to the analysis of practical building frames. He is highly mindful of the labor involved in the preparation of these valuable discussions.

Professor Witmer's discussion refers primarily to the determination of the moments caused by column deformation. He states correctly that this effect can be evaluated with the effect of horizontal translation, but it should be noted that this procedure is possible only when the fixed-end column moments are obtained from a preliminary estimate of deflections and approximate column stresses are known.

Mr. Timby requests the answers to several questions which the writer attempted to answer in the original paper. Of course, it is not true that the preliminary location of points of contraflexure at the mid-heights of the columns, or the temporary assumption that the story deflection is proportional to the story height, carries through the entire analysis and vitiates the final results. These assumptions merely form a starting point in the analysis. The simplified method is based on successive corrections, and the final moments can be calculated to agree with any predetermined standard of accuracy.

Perhaps it is unfortunate that the word, "ideal," was used to describe a bent theoretically proportioned so as to deflect linearly. However, no suggestion was made that such a frame was desirable. In fact, its only purpose was to help the reader bridge the gap from the single-story bent to the tall building frame. Mr. Timby seems to have misunderstood the purpose of this part of the paper and digresses into a comparison of the ideal frame with a mechanical model in which he was particularly interested.

The results of the analysis of this model by means of the Beggs deformeter by Messrs. Coultas and Lawton were used by both Mr. Timby and Mr. Wilbur in drawing certain rather important conclusions. This was particularly unfortunate since it can be shown that the Coultas and Lawton analysis of this model bent is radically in error.

---

[34] Prof., Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

The Coultas and Lawton bent was intended to represent a practical six-story building frame. Hence, the columns change section above the girder line, and the girders are reduced in cross-section near the columns. Thus, the analysis is complicated by intra-panel change in cross-section as well as by the fact that the wind force is taken as distributed over the windward column. An approximate analysis can readily be made by the simplified method by concentrating the loads at the floor levels and by using average *K*-values to represent the stiffness factors of the members.

The true carry-over factors and the distribution factors at the joints will be affected by intra-panel changes in cross-section. In order to obtain a more exact analysis than would result from average *K*-values, the actual factors should be used. Furthermore, the effect of the distributed loading in producing additional fixed-end moments in the windward column must be considered. Such analyses were performed, but are not included herein. It is sufficient to state that a comparison of column moments determined by four such analyses with those determined by Messrs. Coultas and Lawton, are given in Table 11 and show the latter to be so radically different from any of the others that one can only conclude that they are entirely valueless.

Since Mr. Timby's further observations and questions were based upon his study of this incorrect deformeter analysis, it seems unnecessary to take further space for their consideration. Mr. Wilbur observed that the deformeter analysis must take incorrectly into account the effect of direct stress and shearing deformation, but he was properly not convinced that this effect plus the effect of the distributed load could account for the unusual results shown in his Table 10. Table 11 shows the effect of load distribution and of intra-panel change in cross-section, and deflections measured on a model by Mr. M. P. Frank (formerly Instructor in the Civil Engineering Department of the Agricultural and Mechanical College of Texas, College Station, Tex.), prove that the effect of direct stress and shearing deformations are not serious for this particular bent. Lateral deflections computed by different methods were determined by Mr. Frank as shown in Fig. 18, in which Curve 5 represents the deflections computed from final moments obtained by the simplified method, using distributed loading and members with varying cross-sections. The deflection curve computed from the moments obtained by the slope-deflection method is identical with Curve 3, Fig. 18, of estimated deflections.

In regard to load distribution, the writer would like to emphasize the point that actual wind loading is not distributed entirely to the column. In fact, where the panel is 20 ft wide by 12 ft high, about two-thirds of the total wind pressure is concentrated at the floor levels by the spandrel beams, and, if the walls do not fit tightly against the columns, practically all the wind pressure may be thus concentrated. Hence, the writer feels that the moments of Column (5), Table 11, represent the most probable set of values. Mr. Wilbur seems to concur in this opinion.

Mr. Letherbury studied an interesting step-back frame by the simplified method and by the Bowman method. Despite the set-back, this is an extremely regular frame, which accounts for the small error (20%) shown by the statically determinate (Bowman) method. No such agreement could be expected where the variation of K-values corresponds to a normally irregular frame. Mr. Letherbury makes a valuable suggestion in regard to the use of the writer's method of estimating deflections for the study of tower deflections and vibrations.

Mr. Weiss emphasizes the time consumed by the wind-stress analysis of a tall building. He observes that the 56-story Irving Trust Company Building contains 6 200 wind-resisting members in its entire frame. The writer counts about 620 members in a single bent, as shown in Table 5, and, hence, he concludes that there must be about ten such bents. In a very regular building all ten such bents may be practically identical, but it will be assumed that there are ten variations to be analyzed separately. A wind-stress analysis of a tall frame can be performed by the simplified method in considerably less than 10 min per member. The time consumed would be about 500 hr if the frames were so irregular from top to bottom that a statically determinate analysis could not be used over any part of the frame. Is it unreasonable to detail five men for two or three weeks to obtain such information? Can not they be allowed two or three months, if necessary, in which to produce a frame truly proportioned to resist wind stresses in an economical manner? If the structural frame is irregular, is not the engineer justified in spending 0.1% of the cost of a skyscraper in really solving the wind-stress problem?

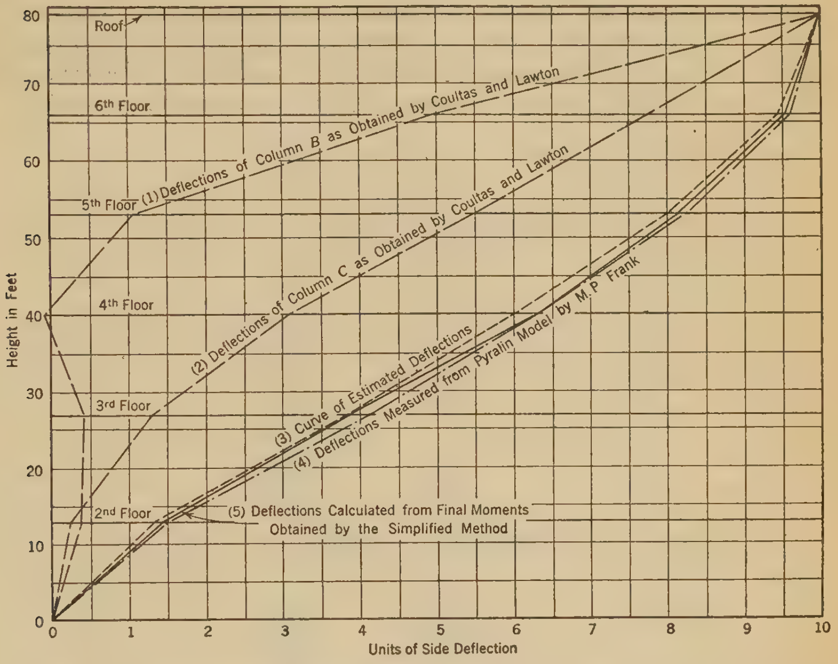

FIG. 18.—COMPARISON OF LATERAL DEFLECTIONS FOR COULTAS AND LAWTON BENT.

Mr. Weiss feels that the writer has "overlooked one of the peculiar characteristics of modern tall buildings." He refers to the use of stiff columns and slender girders in the lower stories. On the contrary, the simplified method was designed to apply to all such cases. Fig. 13 is purported to show that the task of applying the simplified method to a structure such as the Irving Trust Company Building would become an impossible undertaking because of slowness of convergence of moments. The writer believes that Mr. Weiss confused the simplified method and the general method of successive corrections, as adopted by Sub-Committee No. 31, Committee on Steel, of the Construction Division, on Wind-Bracing in Steel Buildings, because his criticism would be applicable to the latter, but not to the former. To show that the application of the simplified method to a frame with stiff columns and slender girders is not "such a Herculean undertaking as to overshadow completely the task performed by Professors Wilson and Maney in solving sixty simultaneous equations," the writer has analyzed the frame shown in Fig. 19. This frame maintains the same essential features of stiff columns and slender girders found in the Irving Trust Company Building. Deflections are estimated in Table 12 and moments are balanced in Fig. 20. An interesting characteristic is the development of negative moments at the top of the lower-story columns, which, incidentally, necessitated the introduction of correction moments into Story 1. However, the labor involved in the analysis is not particularly greater than would be necessary for a bent with relatively stiff girders. A time allowance of 10 min per member is ample.

FIG. 19.—PROPERTIES OF FRAME HAVING STIFF COLUMNS AND FLEXIBLE GIRDERS.

Mr. Reese has contributed a valuable study comparing the simplified method with several other methods in its application to the analysis of a practical 15-story reinforced concrete building frame. The study was particularly useful in that the frame was irregular. Apparently, this investigation favorably impressed Mr. Reese with the usefulness of the simplified method as a time-saving device.

Mr. Floris seems to be rather vague as to the application of the simplified method of wind-stress analysis. Perhaps that is why he remains faithful to the classical method of simultaneous equations. He errs in classing the Cross

* Moment division where first floor girder is relatively slender.

method of balancing moments as fundamentally less accurate than the slope deflection method, and he is further mistaken in assuming that the simplified method is tedious in practical cases, as has been shown by several discussers. Contrary to Mr. Floris' viewpoint, the writer feels that the importance of the elementary arithmetical procedure of the simplified method needs further emphasis.

Mr. Gedo is correct in emphasizing the importance of direct stress deformations on the moments in a Vierendeel truss, although the writer made no error in stating that direct stress deformations usually are neglected. The writer made an exhaustive study of this problem several years ago[35] and the conclusions reached were in agreement with Mr. Gedo's observations. Mr. Gedo might have saved himself considerable time by using the simplified method instead of the method of least work in solving his example. The effect of direct stress deformation is easily introduced into the analysis by the simplified method.

Mr. Skytte offers several rather complicated formulas for locating points of contraflexure and for determining girder shears in connection with a deflection estimate. The writer does not question the accuracy of such formulas, but wonders when they would be useful. The simple method of estimating deflections as given in the original paper has proved to be quite satisfactory; even rather startingly so. (See Figs. 18 and 21.) In fact, the writer would suggest that the method be simplified by omitting the use of the r and n-ratios, except in irregular stories as shown in Table 12. No practical case occurs to the writer in which greater precision would be neecssary.

---

[35] Thesis presented to the Univ. of Illinois in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Engineering.

Mr. Richards is disturbed about the time consumed by the trial-and-error method for the design of a building frame. He suggests that in structural members, such as beams or columns, one proceeds directly to the selection of size and asks for a similar direct procedure for tall building design. The writer believes that this is equivalent to asking for the moon. A building frame is an indeterminate structure in which the moments are controlled by deflections. One must "have" a building before he can analyze it.

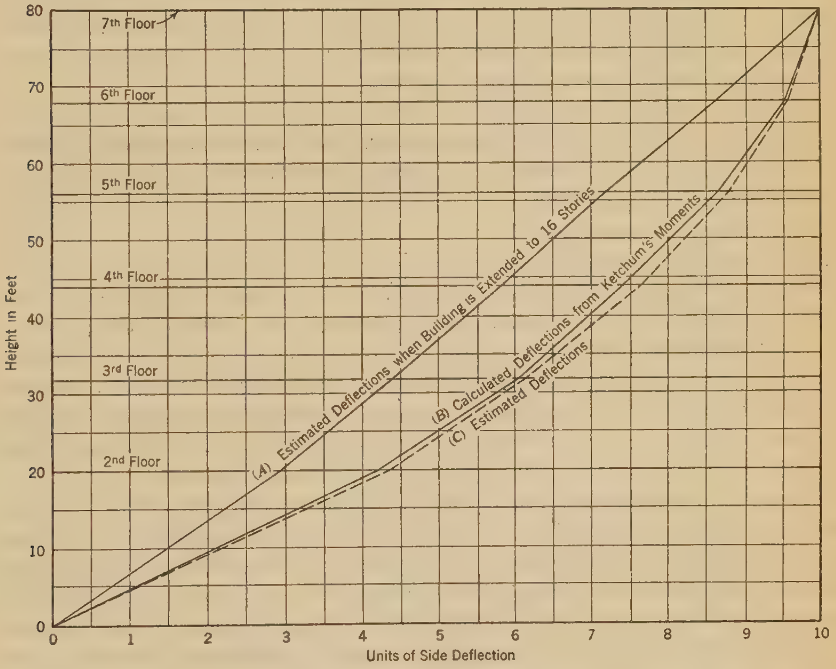

FIG. 21.—COMPARISON OF LATERAL DEFLECTIONS FOR THE KETCHUM FRAME.

There is a possible answer to Mr. Richard's question; namely, a building might be proportioned to justify the assumptions of a statically determinate method of analysis; then the true wind moments would be as assumed and the design would be completed in a single operation. The only difficulty here is that "the tail is wagging the dog." A method of analysis is set up on a pedestal, and the more important procedure of design is relegated to the background. The designer can study economical proportions only through a limited range and a truly economical structure is seldom possible. It is surely wasteful always to force points of contraflexure to the centers of members, and to attempt to suggest to the structure which members shall carry direct stress, approaches the impossible unless the frame is very regular.

There seems to be a popular fetishism to this ideal of design, but the writer doubts that it will survive or even that it can be strictly applied to an irregular frame.

Like most extremely practical men, Mr. Spurr has so frequently encountered difficulties produced by structural details that he may perhaps tend to under-emphasize the usefulness of a theoretical tool of analysis just as a college professor may tend to over-emphasize its importance. When one is faced with the daily realization that angles, split beams, and knee-braces must be used more or less indiscriminately, and that all are commonly assumed to produce rigid connections when the structure is analyzed (which, of course, is not true) the assumption of points of contraflexure at the mid-height of columns takes on a less serious aspect. However, despite these disturbing factors, the writer prefers to place his faith in a method of analysis that takes elastic deflections into account.

Mr. Spurr errs in stating that the author has not established a method of caring for the effect of column deformations. The matter receives full attention under the heading, "Effect of Column Deformation." The evaluation of the effect of column deformation is not difficult when a second analysis follows revision of proportions.

Mr. Fleming supports, at least partly, the writer's contention that the method of successive corrections, of which the simplified method is one variation, is "feasible" for application to practical tall building design where the slope deflection method and the other classical methods were beyond reasonable use. The writer considers this particularly significant, because Mr. Fleming's statically determinate methods are those that careless designers are likely to try to use on irregular structures, whereas Mr. Fleming himself states that irregular structures "should receive special study."

The six-story bent analyzed by M. S. Ketchum, M. Am. Soc. C. E., is mentioned by Mr. Fleming[25] as showing a variation of criterion ratios from 5 to 50% when analyzed by the simple method of balancing K-values. His statement is correct, but perhaps misleading to some readers. No different result could be expected. The balancing of K-values is based on the assumption of a straight-line (or gradually curved) deflection diagram. The Ketchum bent shows a variation of 20 to 1 between the total moments in the first and sixth stories, while the K-values of the columns are scarcely doubled and the girders are unchanged. A tall building, on the other hand, shows a corresponding increase in K-values and story moments from top to bottom. The tall building will commonly approach a straight-line deflection curve while that for the Ketchum bent will be roughly parabolic.

The curves of Fig. 21 are deflection diagrams for the Ketchum bent. The two similar curves (B and C) represent the deflection of the six-story bent as estimated by the writer's method and as calculated from the Ketchum moments. The agreement between these curves shows that the moments obtained by the simplified method (based on the estimated deflections) would check the Ketchum moments closely. The third curve (A) approaches a straight line and is the estimated deflection diagram for the lower six stories of Professor Ketchum's bent if it is extended upward to form a 16-story building. Note that for this practical case the deflection curve does approach a straight line and the moments could be obtained within a range of error of 10% by following the procedure of balancing *K*-values, as illustrated for the American Insurance Union Building, in Fig. 5. Correction moments would be required in the lower story only. Incidentally, it seems that the idea of introducing correction moments made little impression on the discussers. Experience will show that this is one of the most valuable tools of the simplified method.

Standard Equipment for Evaporation Stations: Final Report of Sub-Committee on Evaporation of the Special Committee on Irrigation Hydraulics 716

With Discussion by Messrs. Ralph R. Randell, C. E. Grunsky, Charles H. Lee, S. T. Harding, L. Standish Hall, Adolpho Santos, Jr., John W. Pritchett, Ivan E. Houk, R. I. Meeker, Carl Rohwer, Robert Follansbee, and Sub-Committee on Evaporation, Special Committee on Irrigation Hydraulics.

Note.—Published in February, 1933, *Proceedings*.

FOREWORD

These two papers and the recommended list of standard equipment constitute the Final Report of the Special Committee on Irrigation Hydraulics on the subject of evaporation. The Symposium has been developed since the submission of the work done by Mr. Rohwer, which was accepted for publication as a separate paper. The official report of the Sub-Committee on Evaporation, covering only the subject of standard equipment, was next added; and, finally, Mr. Follansbee's contribution was accepted to round out the entire subject.

The Committee has had as one of its subjects for investigation that of Evaporation from Reservoirs. One of the primary objects of that work has been to find a suitable set of coefficients by which the great variety of existing data on evaporation could be corrected, to the end that evaporation from a large water surface could be expressed in terms of that from the various types of pans in use.

The first objective has been fulfilled in the paper by Mr. Rohwer and the second by the report of the Sub-Committee on Evaporation. Mr. Follansbee's paper serves the purpose of applying the findings regarding pan evaporation to reservoirs. A great mass of detailed information, comprising 200 or more tables, with monthly evaporation records, has been placed on file by Mr. Follansbee, at Engineering Societies Library, 29 West 39th Street, New York, N. Y. These records contain data pertaining to evaporation from reservoirs all over the United States and in many other parts of the world.

The Special Committee on Irrigation Hydraulics has approved the report of the Sub-Committee on Evaporation unanimously and, further, recommends that these standards be followed wherever new evaporation stations are to be installed or old ones re-equipped.

EVAPORATION FROM DIFFERENT TYPES OF PANS

By Carl Rohwer,[1] Assoc. M. Am. Soc. C. E.

Synopsis

The rate of evaporation from different types of pans varies widely and before the evaporation data can be used in estimating the loss from large bodies of water, it is necessary to know the ratio between the evaporation from the type of pan used and that from a large water surface, or the relation between the evaporation from the pan and some pan for which the ratio of the evaporation to that from a large water surface is known.

A summary of the results of the available records, where a comparison has been made between the evaporation from different types of pans or between the evaporation from a pan and a large water surface under similar conditions, is given in this paper, together with recommendations as to the best types of pan to use under different conditions, and the procedure to be followed in taking the observations.

Introduction

Available records of evaporation from pans of different types, or from pans and large water surfaces under similar conditions, are either scattered through many publications or are buried among the unpublished records of various organizations. The writer has assembled such data and re-arranged them for presentation in tabular form. Credit is given in every instance to the publication or agency from which the record was obtained. The tables are published as an Appendix to the paper.

Comparative Results

The records of the comparisons between the evaporation from many types of pans were taken (see Appendix), but particular attention was given to the pans most commonly used, such as the United States Weather Bureau Class *A* land pan and floating pan, the Colorado sunken pan, the United States Geological Survey floating pan, and the United States Bureau of Plant Industry sunken pan. Comparisons were also made, where records had been taken, between the evaporation from these pans and from large bodies of water. In addition to the record of the evaporation, all meteorological data pertaining to each tank were included. Where possible the data at the station were used, but when no records had been kept, the data were taken from the records of the nearest Weather Bureau Station.

---

[1] Associate Irrig. Engr., Colorado Experiment Station, Fort Collins, Colo.

All the records have been summarized and only the mean data are included in this paper. In some cases merely the means for the entire period of the observations are given, but where sufficient records are available the monthly or the daily means are reported. The daily means are given only in those cases where intensive studies of evaporation were made for short periods, and where the observations were taken at frequent intervals during the day.

None of the records has been eliminated, nor have any observations been discarded, except where the original records indicate that the observations are in error. It was assumed that the observations were correct, except as noted, and that differences in the results were due to variations in the setting or the conditions under which the pans were exposed. Consideration was given, however, to the fact that the records from floating pans are less reliable than those from land pans on account of the difficulty in making accurate readings of the evaporation loss, and also because during wind storms water frequently splashes into the pan from the reservoir, or splashes out of the pan when there is a pronounced swell after a storm.

The comparisons of evaporation from pans and from large water surfaces are few and the results are uncertain because of the difficulty in segregating the evaporation from the other losses. Experiments on the evaporation from pans of different sizes, however, show that the size of the pan has a proportionately less effect on the evaporation as the size of pan increases. This fact is used as the basis for determining the relation between the evaporation from pans and from large water surfaces. The comparative data on the evaporation from reservoirs and from pans similarly exposed are presented to show how closely the facts are in accord with the theory, and also to give some idea as to the variation that may be expected in the results.

In reporting the data all the known details concerning the setting of the pans and the conditions under which they operated, are included. Unfortunately, many details are frequently lacking in the reported data. Under these circumstances, if there are discrepancies in the results the reasons for them can only be conjectured.

The tables giving these data are arranged according to the types of pans. All tables showing the comparison of one type of pan with various other types are grouped together. From the mean values taken from these tables, a summary of all the results in which a comparison with any of the standard pans was possible, was prepared. These mean ratios are not the means of the monthly ratios, but are the means of the ratios of the total evaporation losses from the pans.

The experiments[2] made by the late R. B. Sleight, Assoc. M. Am. Soc. C. E., at Denver, Colo., during 1915, 1916, and 1917, cover a wide range of conditions, and the results obtained are uniformly consistent. In using the ratios for the floating tanks, however, it should be kept in mind that the floating pans were not placed at the same point as the land pans and that results similar to those obtained elsewhere can not be expected. The obser-

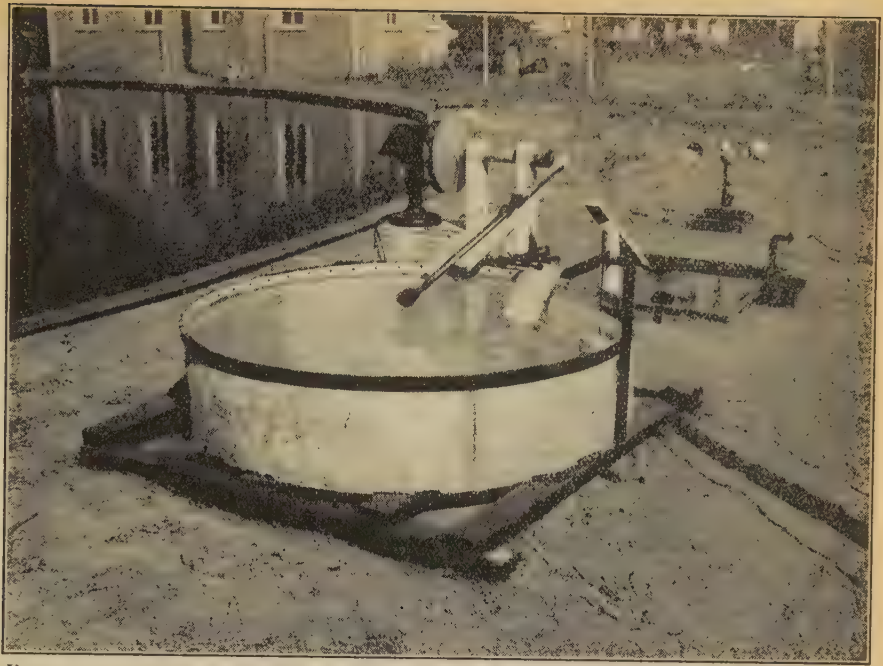

Fig. 1.—U. S. Weather Bureau Class A Land Pan, Colorado Sunken Pan, and 86-Foot Circular Reservoir and Auxiliary Equipment at Fort Collins, Colo.

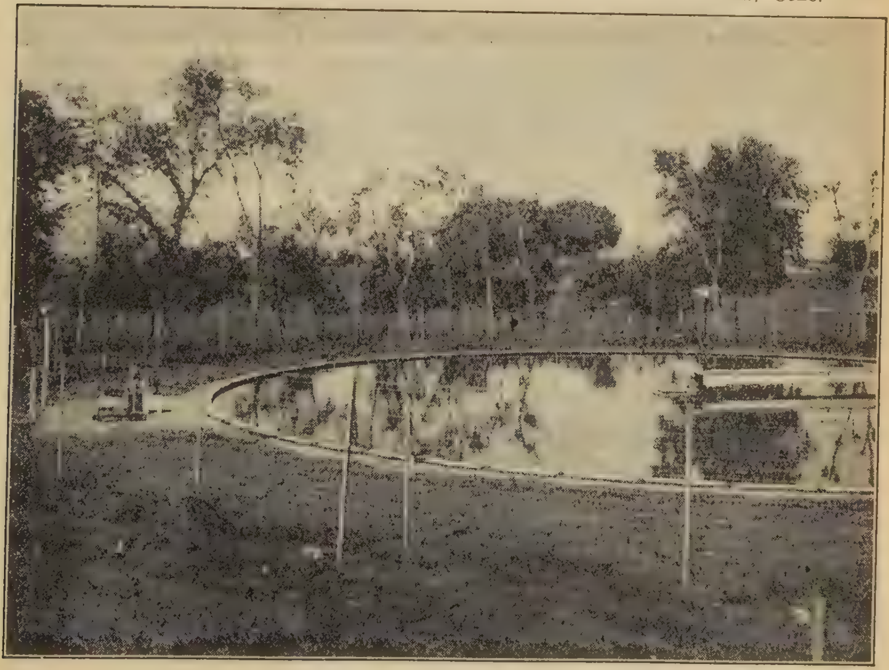

Fig. 2.—Arrangement of Equipment for Conducting Experiments on the 85-Foot Circular Reservoir and Various Standard Pans at Fort Collins, Colo.

vations of floating pans may be compared with each other, however, as they were all subjected to the same conditions.

The comparisons of the evaporation from different types of pans with that from the 85-ft circular reservoir at Fort Collins, Colo., are the results of a large number of observations made under carefully observed conditions. The observations cover three seasons. During the first two seasons, the readings were taken four times daily at 6-hr intervals, and during the last season they were taken three times daily. The 85-ft reservoir used in making the comparison was lined with copper to insure water-tightness. Carefully calibrated instruments were used in taking the observations. It is believed that the results of these comparisons are representative of the conditions under which they were taken. The equipment used in making the study is shown in Figs. 1 and 2. In Fig. 2, the Geological Survey floating pan is shown in the center of the reservoir.

The evaporation from East Park Reservoir and from the various evaporation pans at Stonyford, Calif., was compared under conditions that were favorable for obtaining reliable results. East Park Reservoir is in a practically water-tight basin, and during the period of the tests there was no precipitation and practically no inflow or outflow. Evaporation readings were taken twice daily. The results obtained are in accord with those found at Fort Collins and Denver, except in the case of the floating pan at Denver, and as previously stated, the land and floating pans at Denver were some distance apart. Figs. 3 and 4 show the evaporation pans at East Park Lake.

The ratios of the evaporation from the Weather Bureau Class *A* land pan and the Colorado sunken pan to the evaporation from the 12-ft circular sunken pan at Denver, the 85-ft circular reservoir at Fort Collins, and the 1 800-acre reservoir at Stonyford, are almost identical. Therefore, it is evident that between these limits (surfaces of 113 sq ft and 1 800 acres), there is no decrease in the evaporation per unit area as the size of the water surface increases. These conclusions are confirmed by experiments at Milford, Utah, on the evaporation from a Weather Bureau Class *A* land pan and a 12-ft circular sunken pan. In view of the fact that these observations were made at widely separated points, it may be assumed that these ratios are constant. If these conclusions are correct, it is possible to compute the evaporation from a lake or reservoir when the evaporation from any type of pan for which the ratio has been determined, is known.

OTHER RESERVOIR EVAPORATION COMPARISONS

A comparison of the evaporation from a buried pan and the total loss from Newell Reservoir, Alberta, Canada,[3] by the Department of Natural Resources of the Canadian Pacific Railroad for the period, 1919 to 1925, shows that on the average the total loss from the reservoir is 95% of that from the land pan. The season ratios, however, vary from a minimum of 77% to a maximum of 116 per cent. This large variation is probably due to the fact that the loss from the reservoir was determined from the seasonal inflow, outflow, precipitation, and change in elevation. Errors in any of

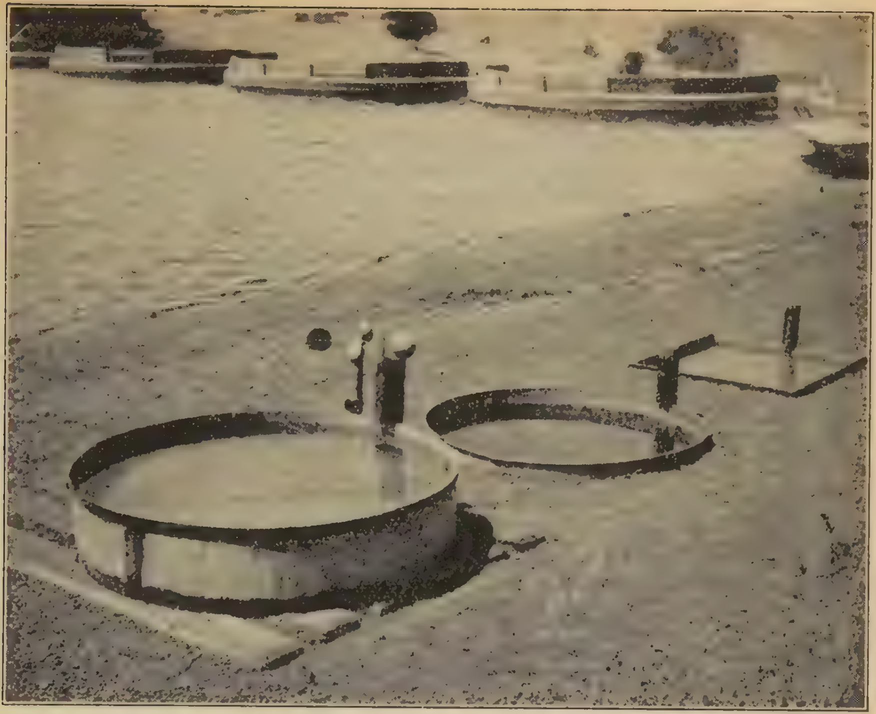

FIG. 3.—U. S. WEATHER BUREAU CLASS *A* LAND PAN, 4-FOOT CIRCULAR SUNKEN PAN, AND COLORADO PAN, AT EAST PARK RESERVOIR, STONYFORD, CALIF.

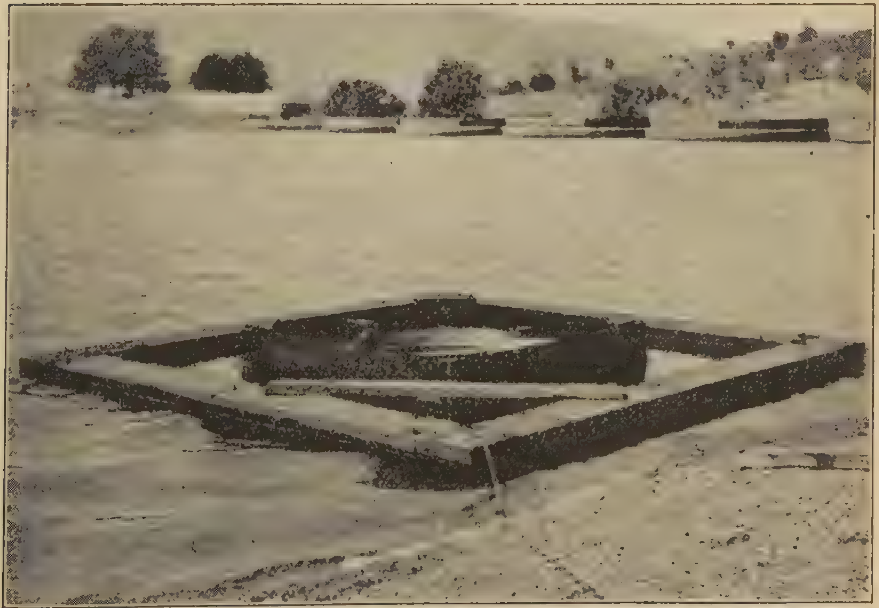

FIG. 4.—U. S. WEATHER BUREAU CLASS *A* LAND PAN USED AS A FLOATING PAN AT EAST PARK RESERVOIR, STONYFORD, CALIF.

these factors would be charged to evaporation. Newell Reservoir has an area of 16 430 acres at Elevation 2 485, and an available capacity of 189 000 acre-ft. The evaporation pan was 4 ft in diameter and 2 ft deep. It was sunk in the ground to within 2 in. of the top, and the water was maintained at the ground level. The pan was located near the shore of the reservoir.

Experiments during 1904 and 1905 by Duryea[4] on the evaporation from land and floating pans in the Santa Clara Valley, California, show that the average evaporation from the floating pans is 71% of that from the land pan. This value is based on the average results from six land pans and three floating pans divided into two groups. The values of the relation varied from a minimum of 55% to a maximum of 85 per cent. All pans were 3 ft square and 12 in. deep and the depth of water was approximately 10 in. The land pans were embedded in the ground and banked with earth nearly to their rims. The floating pans were floated on the Laguna Seca and, apparently, were freely exposed to the air.

Experiments were reported by S. T. Harding,[5] M. Am. Soc. C. E., on the evaporation from Lake Elsinore, in California, and from a pan 3 ft square floating in the lake for the period from May to September, 1916. The results show that the evaporation from the lake is 84% of that from the pan, but that the relation by months varies from a minimum of 63% to a maximum of 114 per cent. The evaporation from the lake was determined from the record of the inflow, outflow, precipitation, and change of stage. The high-water area of Lake Elsinore is 5 500 acres and the elevation, 1 261 ft.

Experiments reported[6] by J. B. Lippincott, M. Am. Soc. C. E., on the evaporation from Lake Hodges and Cuyamaca Lake, and the evaporation from floating pans and land pans are contradictory. The evaporation from Lake Hodges (area, 1 317 acres, and elevation, 315 ft), during six months from June, 1919, to October, 1921, when there was no draft from the lake, was 96% of the evaporation from a sunken pan 3 ft square and 18 in. deep, sunk with the rim flush with the ground and filled with water to within 4 in. of the top. The evaporation from Cuyamaca Lake (area, 978 acres, and elevation, 4 600 ft) during November, 1916, and January, 1919, when there was no draft from the lake, was 108% of that from a floating pan 3 ft square and 18 in. deep, filled with water to within 4 in. of the top. Later, the pan was sunk in the ground and under these conditions, during November, 1921, and June, 1922, the evaporation from the lake was 119% of the pan evaporation. Cuyamaca Lake is surrounded by a large swamp area, and the vegetation in this area may have increased the loss, due to the transpiration from the plants.

Choice of Type of Evaporation Pan

The type of pan chosen for evaporation observations will depend on the purpose of the experiment and on a knowledge of the information available for the different types of evaporation pans. Although a pan may be desirable from several standpoints, it should not be chosen unless the relation of the evaporation from the pan to other types of pans and to large water surfaces is thoroughly established.

[6] *Transactions,* Am. Soc. C. E., Vol. 90 (June, 1927), pp. 356–359.

The types of pans most commonly used in the United States are: (1) The U. S. Weather Bureau Class *A* land pan shown in Figs. 2, 3, and 4; (2) the U. S. Bureau of Plant Industry sunken pan; (3) the Colorado sunken pan (see Figs. 2 and 3); (4) the U. S. Geological Survey[7] floating pan; and (5) the U. S. Weather Bureau floating pan. Each of these pans is built according to definite specifications and has certain advantages and disadvantages. For convenience, these types will be referred to by number in this paper.

Pan (1).—The Class A Land Pan of the United States Weather Bureau.—The Class *A* land pan is used more than any other type, and for general evaporation studies is probably the most satisfactory. This is the standard pan of the U. S. Weather Bureau and is the type used at all its evaporation stations. Other agencies also frequently install this type of pan and follow the Weather Bureau procedure in taking the observations. As shown in Fig. 5, this pan is 4 ft in diameter and 10 in. deep. It is made of 22-gauge galvanized iron and is supported on a grillage of timbers so that the bottom of the tank is 6 in. above the original ground surface. The pan is filled with water to within 2 in. of the top and is refilled as soon as the water has dropped 1 in. below this elevation. A special micrometer hook-gauge is used to measure the evaporation. This gauge is located in a stilling-well which acts as a support for the gauge. The auxiliary equipment consists of an anemometer, a rain gauge, "maximum-and-minimum" thermometers, and an instrument shelter. The readings are taken twice daily at approximately 7:00 A. M. and 7:00 P. M.

The pan is simple in design and easy to operate. Being above the ground, it does not blow full of water in wind storms. The water does not splash into it and the snow does not drift into it when rain or snow is falling. The water in the pan is fully exposed to the air, and follows the air temperatures quite closely. As a result, the evaporation from it changes more quickly with the changes in temperature than from other types of pan. In some experimental work, this is a desirable feature, but the rapid change in the temperature makes it difficult to obtain the true mean temperature of the water.

From the standpoint of making comparisons with known data on evaporation, this type of pan is probably best adapted to the study of evaporation from water surfaces, because a large number of these pans have been installed in the United States, and many observational data obtained under similar conditions with a uniform procedure, are available from them. It is to be regretted that relatively few of these pans have been installed in the eastern part of the United States, and, unfortunately, all the data necessary for making a comparison between evaporation records at different stations are

---

[7] In a letter dated December 11, 1929, N. C. Grover, M. Am. Soc. C. E., Chief Hydraulic Engineer of the U. S. Geological Survey, states that there is no official U. S. Geological Survey floating pan. The pan by that name was designed by E. F. Kriegsman, Assoc. M. Am. Soc. C. E.

not observed by the Weather Bureau. The missing information, however, can usually be obtained from records of near-by Weather Bureau Stations.

Another criticism of this type is that the rate of evaporation is much higher than that from a large water surface under similar conditions, due to the fact that the pan is more fully exposed to the air than the reservoir. For this reason a large correction must be made in determining the reservoir evaporation from the pan record. This factor has been determined, however, under a wide variety of conditions, with very consistent results. Comparisons indicate that a factor of 0.69 or 0.70 should be used in converting the evaporation from the pan to that from the reservoir.

Pan (2).—United States Bureau of Plant Industry Sunken Pan.—The pan shown in Fig. 6 is also quite satisfactory. It is 6 ft in diameter and 2 ft. deep, is made of 22-gauge galvanized iron, and is sunk in the ground so that 4 in. of the rim projects above the ground surface. The water surface is maintained at approximately the elevation of the surrounding ground, and whenever it deviates more than $\frac{1}{2}$ in. from the level, due to either evaporation or precipitation, it is brought back to the standard elevation by adding or removing water. The evaporation from the pan is measured by a special micrometer point-gauge, placed on the stilling-well, which is attached to the outside of the pan. A standard rain gauge, anemometer, and instrument shelter of the Weather Bureau type are a part of each station. Maximum-and-minimum thermometers and a psychrometer are provided for determining the temperature and the relative humidity. The readings are taken daily.

FIG. 6.—U. S. BUREAU OF PLANT INDUSTRY LAND PAN (TYPE (2)).

The Bureau of Plant Industry maintains an evaporation pan of this type at each of its dry land stations in the western half of the United States. Evaporation records, including complete meteorological data, are available at each of the stations up to and including 1916. After this date the water temperature records are lacking. The evaporation from this pan does not vary through as wide a range as that from Pan (1), nor does the temperature of the water follow the air temperature so closely. Since the variation in temperature is less, it is easier to determine the mean temperature. The evaporation is more nearly equal to that from a large water surface, and, consequently, a smaller correction is necessary to determine the evaporation from a large water surface. No direct comparisons are available between the evaporation from Pan (2) and from a large water surface, but comparisons have been made with pans for which this relation is known, and from this information it is possible to determine the factor to be used in computing the reservoir evaporation from the pan evaporation. This factor is given as 0.94 in Table 6, which is discussed subsequently.

Pan (2) is larger and more expensive to build and install than Pan (1) and data are not available from as many localities. Neither is the pan so well protected from splashing rain, drifting snow, and blowing dust and trash, as the Weather Bureau pan, but the fact that the rim is 4 in. above the ground minimizes the effect of these disturbing factors.

Pan (3).—The Colorado Sunken Pan.—The Colorado pan was developed at the Colorado Experiment Station. This pan, shown in Fig. 7, is usually made 3 ft deep, but will give satisfactory results if it is only 18 in. deep. It is made of 18-gauge galvanized iron and is sunk in the ground to within from 2 to 6 in. of the top, depending on conditions. Probably the most satisfactory depth is 4 in., because it tends to eliminate the difficulties due to splashing rain, drifting snow, and the accumulation of dust and trash to a considerable extent without introducing too great a rim effect due to the exposed metal. The water is maintained at the ground level and should not be permitted to deviate more than an inch each way from this level. A hook-gauge is used for measuring the evaporation and a stilling-well should be installed when accurate results are desired. A standard anemometer and rain gauge are provided for measuring the wind velocity and precipitation, and maximum-and-minimum thermometers for the temperature. A sling psychrometer is used to determine the humidity. Readings on the pan are taken twice daily.

The Colorado pan has not been used as extensively as Pans (1) and (2). It has advantages, however, which warrant a wider use of this type. It is cheap and easy to build and install. Due to the fact that the pan is sunk in the ground, the water temperature lags behind the air temperature. In this respect it resembles a large water surface more nearly than Type (1), and is similar to Pan (2). For this reason the mean temperature of the water is easy to determine. The evaporation from the Colorado pan is almost identical with that from a floating pan of the same size and shape, exposed under the same meteorological conditions, and is much easier to maintain.

The correction factor, 0.78 (in Table 6), for computing the equivalent evaporation from a reservoir is between that for Pans (1) and (2). It has been determined under a wide range of conditions with uniformly consistent results.

FIG. 7.—COLORADO LAND PAN (TYPE (3)).

Pan (4).—The United States Geological Survey Floating Pan.—The evaporation pan in Fig. 8, was designed for use in measuring the loss from lakes and reservoirs because it was thought that evaporation from a floating pan would be identical with that from a reservoir, but the experimental results have not substantiated this conclusion. This pan is made of 18-gauge galvanized iron and is supported by two cylindrical metal tubes, so that it floats in the water with 3 in. of the rim above the surface. The water inside the tank is kept at the same depth as that outside. Surging in the pan is reduced by two diagonal diaphragms beneath the water surface, which are perforated with 1-in. holes as shown. In order to protect it from the waves, the pan is surrounded by a raft supported by barrels to keep it from sinking when water-logged. Evaporation is determined by measuring the water required to bring the level to a fixed point which is attached to the intersection of the diaphragms. A special cup holding exactly enough water to raise the level of the pan 0.01 in. is used in making the measurement. When complete meteorological records are desired, the same instruments should be used as are provided for Pan (2).

FIG. 8.—PLAN AND SECTION, U. S. GEOLOGICAL SURVEY FLOATING PAN (TYPE (4))

Being in the water, Pan (4) is protected from drifting snow and is not affected by the splashing of the rain, because as much splashes in as splashes out. Neither dust nor trash can blow into the pan. It is subject to the same conditions as those that occur in the lake or reservoir, and, consequently, the factor for computing the equivalent evaporation from the large water surface should be nearer unity than the factors for the land pans. The experimental results are inconsistent; however, the mean value of the factor is 0.77. The evaporation from the floating pan is almost identical with that from a similar sunken pan (see Table 3(*a*) and Table 6). Since, in comparison with the land pan (Type (1)), Pan (4) is more expensive to construct, more difficult to maintain, and is constantly subject to the danger of being splashed full of water from outside waves or being partly emptied by water splashing out of the tank, due to the rolling of the pan, this type is losing favor rapidly and is being replaced by some type of land pan.

Pan (5).—United States Weather Bureau Floating Pan.—Pans of the Weather Bureau type, as shown in Fig. 4, are sometimes used as floating pans. They have all the advantages and disadvantages of Pan (4), except that they roll more when there is a swell because of their greater size. This condition has been overcome to some extent by building cellular baffles in the pan below the water surface. Evaporation is almost identical with that from a buried pan of similar shape (see Table 1). The constant for converting the pan evaporation to reservoir evaporation has been established as 0.78 (Table 6). Equipment similar to that used at stations of the Bureau of Plant Industry is recommended.

From the foregoing discussion and from the experimental results, Pan (1) seems to be best adapted to the study of ordinary evaporation problems. For special problems, some of the other types of pans may give better results and, under these conditions, the merits of the different pans for the special problem should be investigated. The evaporation from Pan (2) probably approaches that from a large body of water more nearly than any of the other standard pans, but the factor for converting the pan evaporation to the reservoir evaporation is not known as definitely as for some of the other pans. Although this factor has been determined for the Colorado pan (Type (3)) under a wide range of conditions, this type has been used to only a limited extent in evaporation investigations, and, consequently, comparative evaporation records are available for only a few places. As previously mentioned, records observed from floating pans are unreliable, and since the evaporation from a sunken land pan is almost identical with that from a floating pan of the same size, there is no purpose in using a floating pan.

PROCEDURE

The location of the evaporation pan should be given careful consideration; otherwise, comparable and reliable data can not be obtained. The land pans should be installed in level areas unobstructed by trees and buildings, and if the observations are for the purpose of determining the equivalent reservoir evaporation, the location chosen should be representative of conditions at the reservoir. Isolated places, where no satisfactory water supply is available, or where it is not possible to secure the services of an intelligent observer, should be avoided. The equipment should be protected by a close mesh-wire fence. Fig. 5 is a diagram of a completely equipped Class *A* Weather Bureau Station. Although floating pans are not recommended, if it is necessary to install one for any reason, the location chosen should be in an area protected, to some extent, from the full force of the waves. The exposure to the wind, however, should represent the average conditions for the reservoir. The approximate elevation of the area chosen should be known, because evaporation varies with altitude.

The evaporation from the different types of pans is dependent, to some extent, on the color of the pan, and for this reason it is recommended that no paint, tar, or other coating, be used. To reduce the growth of algæ and other plants in the water, the pans should be cleaned at least once a month, and oftener if necessary. Cleaning the tanks also reduces the concentration of salts in the water, which otherwise would occur due to the evaporation.

In order to obtain comparable evaporation data, complete meteorological records should be taken and a standardized procedure should be followed in taking the observations. The meteorological record should include the air and water temperature, the humidity, the wind movement, the precipitation, and the evaporation loss. The following instruments are required:

Two sets of "maximum-and-minimum" thermometers for determining the mean air and water temperature; or
Two ordinary thermometers where observations can be taken at 12-hr intervals, or oftener;
One psychrometer for determining the humidity of the air;
One anemometer for recording the wind movement;
One rain gauge for measuring the precipitation;
One gauge for measuring the evaporation; and
One instrument shelter for the air thermometers and the psychrometer.

The standard Weather Bureau practice should be followed in taking the observations. Complete instructions for the operation of Pan (1) are given in *Circular L* of the Instrument Division of the U. S. Weather Bureau, and observations on the other types of pans should follow the same procedure. The mean water temperature and the relative humidity of the air are not observed by the Weather Bureau at its Class *A* stations, but these observations should be taken. The mean temperature of the water may be determined either by readings of "maximum-and-minimum" thermometers floating in the water with their bulbs immersed $\frac{1}{4}$ in. beneath the surface of the water, or by readings on an ordinary thermometer similarly exposed. The "maximum-and-minimum" thermometers require only a single reading daily to obtain a fair average of the temperature, whereas the ordinary thermometer must be read twice daily at 12-hr intervals for similar accuracy. Maximum thermometers are easily broken, however, and for this reason are not as satisfactory when the readings are taken by amateur observers. Where possible, the sling or rotating psychrometer should be used for determining the humidity, but where the readings can not be taken at regular intervals, a hair hygrometer may be used to obtain approximate results.

The velocity of the wind varies with the elevation above the ground surface. For this reason, a standard anemometer setting should be adopted for each type of evaporation pan in order to obtain comparable results. The standard practice at Class *A* Weather Bureau stations is to mount the anemometers on the grillage of timbers which supports the pan so that the cups of the anemometer are 6 in. above the top of the pan (see Fig. 3). At stations of the Bureau of Plant Industry, the anemometer is placed so that the cups are 24 in. above the top of the pan. Although no standard has been adopted for installing the anemometers at stations where Pans (3) or (4) are used, it is suggested for uniformity that the anemometers be mounted so that their cups are 18 in. above the surface of the ground or the water. Either 3-cup or 4-cup anemometers, of the Weather Bureau pattern, may be used. The 3-cup anemometers are more accurate at high wind velocities, but near the ground the velocities are never so high that the 4-cup anemometer is not sufficiently accurate.

The rain gauge for evaporation stations should be of the Weather Bureau type and should be installed in accordance with the instructions in *Circular L* of the Weather Bureau. The evaporation gauges used in connection with the different pans are usually of special forms, but any gauge giving readings to within 0.001 ft should be satisfactory.

Observations should be taken at 7:00 A. M., according to the recommendations of the Weather Bureau, but where complete and accurate meteorological data require it, the readings should be taken oftener. Observations twice daily at 12-hr intervals (usually at 7:00 A. M. and 7:00 P. M.) give more accurate results, particularly as to the humidity. Where readings can not be taken at regular intervals, recording instruments should be used to obtain the records.

CONCLUSIONS

Records from floating pans are not as consistent or reliable as land-pan records; nor is the evaporation from a floating pan any nearer the evaporation from a large water surface than that from a sunken pan of the same size and shape.

Comparisons between the evaporation from Class *A* land pans of the Weather Bureau (Type (1)) and Colorado sunken pans (Type (3)) with the evaporation from large water surfaces, indicate that there is a definite relation between the pan and reservoir evaporation. For the Class *A* land pan, the factor for computing the reservoir evaporation from the pan evaporation is between 0.69 and 0.70, and for the Colorado pan, it is 0.78.

Comparison of the evaporation from different types of pans with that from large water surfaces of different sizes, shows that the size of the pan has a proportionately smaller effect on the evaporation as the size of the surface increases, and that when the diameter is greater than 12 ft, the size of the pan has practically no effect on the evaporation.

When all factors are considered, Pan (1) is probably better suited for evaporation investigations than the other evaporation pans. In order to obtain comparable evaporation results, standard equipment installed under representative conditions should be used, and a standard procedure should be followed in making the observations.

ACKNOWLEDGMENTS

The author wishes to acknowledge the co-operation of those agencies and individuals who furnished evaporation data from their unpublished records, or who gave other information about the experiments.

APPENDIX

Summary of Data on Evaporation from Water Surfaces

For convenience of reference in this Appendix the various pans used in evaporation studies are identified by numbers as defined in the paper. For example, Pan (1) is the Class *A* land pan of the U. S. Weather Bureau, shown in Figs. 1 and 5; Pan (2) is the sunken pan of the U. S. Bureau of Plant Industry, shown in Fig. 6; Pan (3) is the Colorado sunken pan shown in Figs. 1, 3, and 7; Pan (4) is the floating pan of the U. S. Geological Survey shown in Fig. 8; and Pan (5) is simply Pan (1) used as a floating pan, as shown in Fig. 4.

East Park Reservoir, Stonyford, Calif.—The data in Table 1 are from records of the Bureau of Agricultural Engineering, United States Department of Agriculture, for observations made in July, 1930.[8] Water was maintained at a level approximately 2 in. below the rim in Pans (1) and (3). In Pans (2) and (4), the level was 3 in. below the rim.

TABLE 1.—Evaporation from Reservoir Compared with That from Pans; East Park Reservoir, Stonyford, Calif.

* Data for the period beginning July 19, 1930. The corresponding evaporation from the reservoir for the same period is 7.162.

Pans (2) and (3) were buried to within 3 in. and 1 in. of the top, respectively. Pan (1) was installed on a grillage of timbers, and Pan (5) was fixed in a raft. In Column (9), Table 1, all the anemometer readings have been reduced to surface velocities. East Park Reservoir is in a water-tight valley, geologically. Its elevation is 1 200 ft.

Comparison of Evaporation from Pan (1) and Various Other Types of Pans.—The data in Table 2 are largely self-explanatory. In Table 2(*a*) a comparison is afforded between evaporation from Pans (1) and (2) (see Columns (8) and (9)), a Class *A* land pan, and a sunken pan. This part of Table 2 was compiled from information presented[9] by Ivan E. Houk, M. Am. Soc. C. E., covering observations made during 1926, 1927, and 1928. Pan (1) was the standard type shown in Fig. 5, while Pan (2) was 4 ft in diameter

and 2 ft deep, with 3 in. of the tank above ground. Water in Pan (2) was maintained at ground level. The anemometer cups were fixed 24 in. above ground, and readings were taken generally at 5:00 P. M. Los Griegos, N. Mex., is at an elevation of 4 970 ft.

Table 2(*b*) is from unpublished data in the office of the State Engineer of Colorado, made available through the courtesy of R. J. Tipton, Assoc. M. Am. Soc. C. E. Observations were made in 1927, 1928, and 1930. Pans (1) and (2) were the same dimensions as given in Table 2(*a*), with the difference that Pan (2) was buried to within 2 in. above ground. Mariotte control apparatus[10] was used to maintain the level in the pans. A 3-cup anemometer was fixed at 18 in. above the ground. Garnett, Colo., is at Elevation 7 700.

---

[10] For description, see *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 962.

Table 2(*c*)[11] is from data observed during the four years, 1917 to 1920, inclusive. The Briggs pan (Type (2)) was 7:5 ft in diameter and 2.0 ft deep, and was set with the rim flush with the ground. Water was maintained 4 in. below the rim in both pans, and the anemometer cups were 5 in. above Pan (1). The relative humidity readings in Column (6) were taken at Lincoln, Nebr. (3 miles from the pans) at 7: 00 A. M. and 7: 00 P. M. The pans, in this case, were at Elevation 1 150.

Table 2(*d*)[12] is from data observed during the three years, 1925, 1926, and 1927. Pan (2) was 12 ft in diameter, was set with the rim 3 in. above ground, and the water was maintained at ground level. The relative humidity in Column (6), Table 2(*d*), was taken from the record of Modena, Utah. Evaporation readings were taken at 8: 00 A. M. The elevation of Milford, Utah, is 4 962.

Table 2(*e*) shows[13] some data and observations made during the three years, 1921, 1922, and 1923. Water in the floating pan, Type (5), was 6 in. deep, and the surface was maintained at the same elevation as the water in the reservoir. This pan was 350 ft from shore; the land pan, Type (5), was on a small knoll, 100 yd from shore. Anemometer readings were begun in 1922, with standard setting. Precipitation records (Column (4)) are those of Malta, Mont., and the relative humidity (Column (6)) readings are those at Havre, Mont. Nelson Reservoir is at Elevation 2 215.

The data pertaining to the floating pans in Tables 2(*f*) and 2(*g*) are from unpublished records furnished by the courtesy of the U. S. Weather Bureau. The land-pan records are from Climatological Data, California Section, U. S. Weather Bureau. The data in Table 2(*f*) were recorded during 1921. The land pan (Type (1)) was placed on a knoll and was filled with water to about 7 in., the anemometer cups being 6 in. above the rim. Observations were taken daily at 7: 00 A. M. The floating pan (Type (5)) was exposed n a raft and filled to a depth of 6 to 7 in. of water. Oakdale, Calif., is at Elevation 215.

Data in Table 2(*g*) were recorded during the five years, 1925 to 1930. The land pan (Type (1)) was filled with water to a depth of about 7 in., anemometer cups being 11 in. above the rim. The floating pan (Type (5)) was submerged 4 in. and was filled with water to a depth of 6 in. Observations were taken daily at 7: 30 A. M. Fall River Mills, Calif., is at Elevation 3 340, and the ground surrounding the station is flat.

Comparison Between Evaporation from Different Sizes of Pans.—Data compiled in Table 3(*a*) are from records of the U. S. Bureau of Agricultural Engineering, covering the years 1926, 1927, and 1928.[8] The wind velocity given is at the surface of the ground or water in each case. The wind velocities for Pans (3) and (4) are the same as for the reservoir. The elevation of Fort Collins, Colo., is 5 000 ft.

* Days. † Period ending. ‡ Per 24 hours.

Tables 3(*b*) and 3(*c*) were compiled from unpublished data for 1910 furnished by the courtesy of the U. S. Weather Bureau. The pans in Table 3(*b*) were floated on a raft in an arm of the Salton Sea (approximate Elevation − 210), and were kept well immersed. The anemometer cups were approximately 8 in. higher than the rims of the pans.

The land pans in Table 3(*c*) were set on a platform 8 or 10 ft above the Salton Sea (approximate Elevation − 200), about ½ mile from the shore. Water was maintained in them at a depth of approximately 7 in. The anemometer cups were approximately 8 in. higher than the rims of the pans.

* Intermittent periods. † Square. ‡ Above ground. § Depth not given, but assumed to be standard.

Tables 3(*d*) and 3(*e*) are from unpublished records of 1910 furnished by the courtesy of the U. S. Weather Bureau. Water in the pans was maintained at an approximate depth of 8 in. In Table 3(*d*) anemometer cups were approximately 7 in., and in Table 3(*e*), 8.8 in., higher than the rim. The water surface was fully exposed. Brawley, Calif., is at Elevation − 110, and Mecca, Calif., is at Elevation − 189.

Comparison Between Evaporation from 12-Foot Circular Sunken Pan (Type (2)) and Various Other Types.—All the data in Table 4 were observed at Denver, Colo. (Elevation 5 346), during the years 1915, 1916, and 1917.[14]

---

[14] Comp. from *Journal of Agricultural Research*, Vol. X, No. 5, July 30, 1917, and from *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), Table 15, p. 308.

General Comparisons: Land Pans and Floating Pans.—Table 5(*a*) has been compiled from three sources: *Bulletin 9* of the Department of Engineering, State of California; Climatological Data, California Section, U. S. Weather Bureau; and, *Transactions,* Am. Soc. C. E., Vol. 90 (June, 1927). Buena Vista Lake has an area of about 10 000 acres and is at Elevation 420. The observations were made in 1920, the temperature and precipitation records being taken at Bakersfield, Calif. The land pan—Type (3)—was sunk to within 3 in. of the top; the floating pan—Type (4)—was always submerged to within 6 in., of the top, or less. The depth of water was maintained at 3 in. below the top of both pans.

Table 5(*b*) is compiled from records in the *Water Supply Papers* of the U. S. Geological Survey, collected between 1916 and 1925. The Class *A* land pan (Type (1)) and the floating pan of the U. S. Geological Survey (Type (4)) were both of standard dimensions, as shown in Figs. 5 and 8, respectively. The floating pan was set in a lake 20 by 150 ft and from 8 to 10 ft lower than the land pan. Observations were taken at 7:00 A. M. Austin, Tex., is at Elevation 475.

Tables 5(*c*), 5(*d*), and 5(*e*) are from the set-up of identical pans at Morena Reservoir, Barrett Reservoir, and Lower Otay Reservoir, California, during 1928. The precipitation for all three was taken at the Barrett Dam and the temperature at Escondido, Calif. Some of the records were furnished by the courtesy of H. N. Savage, M. Am. Soc. C. E., and others were taken from Climatological Data, California Section, U. S. Weather Bureau. The elevations of the stations are as follows: Morena, 3 000 ft; Barrett, 1 600 ft; anod Lower Otay, 500 ft, above sea level.

Table 5(*f*) was compiled from data presented[15] by Charles H. Lee, M. Am. Soc. C. E., and from the Annual Reports of the Chief of the Weather Bureau. The floating pan (Type (4)), 3 ft square and 10 in. deep, was placed on a raft in Owens River. Water was kept approximately 2 in. below the rim. The deep land pan (Type (2)) was set with the top flush with the ground. In this pan water was never more than 4 in. below the rim. The shallow land pan (Type (3)) was set with the top 5 in. above ground and the water level was maintained approximately 2 in. below the rim. The anemometer cups were 42 ft above ground. Some of the evaporation records were partly estimated. Independence, Calif., is at Elevation 3 907; the period of record was from 1908 to 1911.

Table 5(*g*) was compiled from published and unpublished data recorded[16] by Mr. C. M. O'Neil, of the Canadian Pacific Railroad Company, during 1923 and 1924. The dimensions of land and floating pans were alike. The land pans were sunk in the ground to within 2 in. of their tops. Water was kept at ground level. In the floating pans, water was kept 4 in. below the rim or slightly above the level of submergence. The anemometer cups were 2 ft above ground. Temperature and wind velocity data were taken from plotted data. Brooks Reservoir, Alberta, Canada (Elevation 2 450), has an area of about 40 acres.

Tables 5(h) and 5(i) are from observations made[17] in 1885, on floating pans of the same type, but of different diameters and depths. All pans were floated in Chestnut Hill Reservoir, Boston, Mass. (Elevation 129), supported by a raft 20 ft wide and 40 ft long. They were filled with water to within 3 in. of their tops and submerged to within 6 in. of their tops (as scaled from photographs). Readings were taken daily for Table 5(h) and hourly for Table 5(i). The anemometer was 30.5 ft above the water surface.

Summary.—Table 6 is a summary tabulation of conclusions drawn from the preceding tables.

EVAPORATION FROM RESERVOIR SURFACES

By Robert Follansbee,[18] M. Am. Soc. C. E.

Synopsis

This paper contains the results of all available evaporation records, not only in the United States and outlying possessions, but also in foreign countries, reduced to reservoir surface evaporation by means of coefficients which are stated for each record. These results are given in summarized form, together with records of temperature, wind velocity, and relative humidity, as far as available. A total of 210 evaporation records are presented.

After the summary the relative effect of temperature, wind velocity, and relative humidity is shown by comparison between pairs of records in which two factors are the same and the third is widely different.

A brief discussion of the variation in evaporation throughout the United States concludes the paper.

Introduction

For many years records of evaporation have been kept by different organizations, which have used pans varying not only in size and shape, but in setting. Few, if any, of these records give directly the evaporation from reservoir surfaces, but must be corrected by coefficients that vary with the size of the pan and its setting. By reducing the records to reservoir surface evaporation, the data in which engineers are chiefly interested will be obtained, and a common basis for comparison of evaporation under varying climatic conditions will be available. The writer has compiled, not only for the United States and its possessions, but also for foreign countries, all evaporation records of which he has knowledge, and with them the available related data on temperature, relative humidity, and wind velocity.

Coefficients to Reduce Observed Evaporation to Reservoir Surface

To reduce the observed evaporation to reservoir surface evaporation, use has been made of Mr. Rohwer's paper, published as a part of this Symposium, which brings together the results of many experiments on the subject.

Of the many evaporation records available, the greater number have been taken by pans of the following types:

(1) The United States Weather Bureau Class *A* pan, which is a circular pan, 4 ft in diameter and 10 in. deep, placed on an open timber platform resting on the ground.

NOTE.—This paper is published with the approval of the Director of the U. S. Geological Survey.

[18] Dist. Engr., U. S. Geological Survey, Denver Colo.

(2) The United States Bureau of Plant Industry pan, which is a circular pan, 6 ft in diameter and 2 ft deep, sunk in the ground with its rim 3 in. above the surface.

(3) The floating pan, which may be either 3 ft square and 18 in. deep, or a circular pan, 4 ft in diameter and 10 in. deep, suspended from an enclosing raft with some form of wooden shield to protect the water in the pan from wave action.

United States Weather Bureau Class A Pan.—In addition to the records cited by Mr. Rohwer, those for the Salton Sea, in California, have been used for an approximate comparison. The work done at Salton Sea during 1909 and 1910 does not lend itself to an exact comparison between evaporation from large water surfaces and evaporation from land pans of the Class *A* type, but the following rough approximation can be made.

A Class *A* pan was placed on a platform 2 ft above the water surface at a point in Salton Sea 7 500 ft from shore. This setting may be considered to approximate that of a Class *A* pan on a wooden platform on the ground. One year's record from this pan showed an evaporation of 106.45 in. The actual evaporation from Salton Sea during that period has been computed variously as 69 to 75 in. With a mean value of 72 in., the coefficient for the Class *A* pan is 72 ÷ 106.45 = 0.68.

Another Class *A* pan was placed on a platform 2 ft above the water surface, at a point in Salton Sea 500 ft from shore. This showed an evaporation of 108.65 in. For this pan the coefficient was 72 ÷ 108.65 = 0.66. The mean relative humidity was 60 per cent.

Table 7 is a summary of Mr. Rohwer's results as well as those at Salton Sea; and of the work of the late R. B. Sleight, Assoc. M. Am. Soc. C. E., at Denver, Colo. In view of the results indicated, the coefficient to reduce the U. S. Weather Bureau Class *A* pan records to reservoir surface evaporation has been taken by the writer as 0.69.

TABLE 7.—COEFFICIENTS TO REDUCE CLASS *A* PAN RECORDS TO RESERVOIR SURFACE EVAPORATION

Location	Years of record	Comparison with	Coefficient	Temperature, in degrees Fahrenheit	Wind velocity, in miles per hour	Relative humidity (percentages)
Denver, Colo.	1915–17	12-ft ground pan	0.70	....	....	64
Fort Collins, Colo.	1926–28	85-ft reservoir	0.70	47	1.6	68
East Park Reservoir, California	1930	1 800-acre reservoir	0.68	80	1.7	47
Milford, Utah	1925–27	12-ft ground pan	0.70	50	4.3	41
Lincoln, Nebr.	1917–20	7½-ft ground pan	0.67	51	4.1	65
Salton Sea, California	1909–10	Indirect method	0.68	....	....	60
Salton Sea, California	1909–10	Indirect method	0.66	....	....	60

It should be noted that the experiments were made under climatic conditions having a range of relative humidity from 41% to 68%, a range in temperature from 47° to 80° F, and a range in wind velocity from 1.6 to 4.3 miles per hour. As an increase of more than one-half in relative humidity and similar ranges in temperature and wind velocities showed little change in the coefficient to be applied to Class *A* pans, it appears that for an increase in relative humidity to 70% or 80%, such as is found in the eastern part of the United States, the coefficient will be substantially the same.

United States Bureau of Plant Industry Pans.—The only direct comparison between a Bureau of Plant Industry pan and a large water surface was that made by Sleight in the Denver experiments, in which he found the coefficient to be 0.94.[19]

Floating Pans.—Theoretically, records from a floating pan of galvanized iron should give closely and consistently the evaporation from the water surface in which it floats. Practically, however, it has been found difficult to maintain accurate records, owing to the action of waves, which causes water to enter the pan or to spill out of it. Furthermore, a constant factor tending to increase the observed evaporation is the wetted strip around the inside of the pan just above the normal water surface, produced by wave action within the pan itself. To show the inconsistency of the results of experiments on floating pans, it is only necessary to reduce the records presented by Mr. Rohwer (to which have been added a few compiled by the writer) to the common basis of reservoir evaporation.

Direct comparisons between (1) floating pans, 3 ft square and 18 in. deep, and (2) floating circular pans, 4 ft in diameter and 10 in. deep, with large water surfaces, show the following results:

Location	Square Pan	Circular Pan
Denver, Colo.	0.88	....
Fort Collins, Colo.	0.77	....
East Park Reservoir, California	....	0.78
Lake Elsinore, California	0.84	....
Buena Vista Lake, California	0.70	....
Upper Otay Reservoir, California	0.87	....

Indirect comparisons by means of records from Class *A* pans give the following results:

Location	Square Pan	Circular Pan
Oakdale, Calif.	....	0.92
Fall River Mills, Calif.	....	0.52
Austin, Tex.	0.89	....
Granite Reef, Ariz.	....	0.81

These inconsistent results are practically the same for both types of floating pans, and an average of all coefficients (except that for Fall River Mills), gives 0.83 as the factor to reduce records from floating pans of the two types considered to evaporation from large water surfaces.

Egyptian Records.—The Egyptian Government has maintained evaporation records at points in the Nile Valley from Alexandria to the Southern Sudan. These records have been taken both by floating pans and Piche evaporimeters used in a meteorological screen. To determine the reduction factors, comparisons between Piche tubes and both floating and land pans were made. As it was not found practicable to experiment with pans larger than 2 m square, that size was used as the best available approximation to an open water surface. At Helwan Observatory, on the hills overlooking the Nile Valley, about 15 miles from Cairo, the factor to reduce the Piche records to a 2-m land pan was found to be 0.66. At Abbassiya, near Cairo, the factor to reduce Piche records to a 2-m floating pan square was 0.50, and, for a 1-m floating pan, the factor was 0.88.

---

[19] "Evaporation on United States Reclamation Projects," by Ivan E. Houk, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 308.

By considering the relation between floating and land pans as given by Sleight[20] in his first report on the Denver experiments and combining these with the Helwan observations, the factor to reduce Piche records to those from a 1-m floating-pan record was 0.59. At Abbassiya, the corresponding factor was 0.57. The engineers of the Egyptian Government, therefore, used a factor of 0.50 for the Piche tubes; for their 1-m floating-pan records they used 0.88. In so doing, it was stated that the evaporation would not be underestimated. The factors were determined for each month of the year and there was no evidence of any seasonal variation, the probable departure of the monthly ratios from the mean of the year being 3% for the pans and 10% for the Piche tubes.[21]

Turkestan Records.—The late Lyman E. Bishop, M. Am. Soc. C. E., who spent two years in Turkestan, furnished evaporation records taken by the Soviet Government since 1920 at experiment stations located at Fergana, Andidjan, Khodjent, and Osh, in the Fergana Valley, in Southern Turkestan. This is a region with an irrigated area of 1 600 000 acres and an additional area of 750 000 acres of seeped land. Although no actual records are available, the temperatures are stated to increase gradually from about 5° F, in January, to 120° to 130° F, in July and August, with a monthly mean for these months of about 95 degrees.

The annual rainfall is from 10 to 12 in., all of which occurs between November and March. It is a region of little wind, and as the valley is almost enclosed by high mountains, the evaporation from the irrigated land on which a large quantity of water is used, and from the seeped land, causes a humid atmosphere, particularly at the evaporation pans.

The evaporation records were taken by pans about 6.5 ft square and 3 ft deep set in the ground. By comparison with Sleight's experiments at Denver, the coefficient to reduce the records to reservoir surface evaporation has been taken as 0.95.

REDUCTION OF PAN RECORDS TO RESERVOIR SURFACE EVAPORATION

The foregoing coefficients (as well as some others determined from Sleight's experiments), which have been used by the writer, are based on mean values covering several months, and are shown by the experiments themselves to vary from month to month. For some types of pans, furthermore, the mean coefficient itself may be considerably in error, as shown by the inconsistent results. It is with these facts in mind that the observed

records have been reduced to the common basis of evaporation from reservoir surfaces, and this fact should be considered in studying the figures given in the accompanying tables.

The records, which were taken by pans for which the coefficients had been determined, have been expanded to the full year where necessary. Where the meteorological data were available, the evaporation for the missing periods (usually the winter months) has been either computed or estimated.

The summary of these records, Table 8, is arranged in geographic order, beginning with the northeastern part of the United States. Following the records of the United States are those for outlying possessions and foreign countries (See Table 8(*v*) to (*z*)).

Omitted from the summary are the records at Lawrence, Boston, and Fall River, Mass., and Rochester, N. Y., which were taken from wooden or fiber tanks, for which no coefficients for reduction to reservoir surface evaporation are available (see Table 9). Of these, the best known are the Boston records, taken by the late Desmond FitzGerald, Past-President and Hon. M. Am. Soc. C. E. From 1876 to 1884, these records were taken by observations on small wooden tanks floating in the Chestnut Hill Reservoir, and as wood does not transmit heat readily, it was found that at times the temperature in the tanks varied as much as 10° F from that of the water in the reservoir itself. The same condition persisted when a large wooden tank, 10 ft in diameter and 10 ft deep, was installed in 1884.[22] A summary of these records as observed is given (Table 8), together with others which can not be reduced to reservoir surface evaporation at this time.

EFFECT OF FACTORS INFLUENCING EVAPORATION

The principal factors influencing evaporation are so interdependent that it is difficult to segregate the effect of any one. The relative effect of the variation in any one factor can be shown by selecting, from the many available records, pairs in which two factors are practically the same and the third is widely different. The difference in evaporation may then be considered a measure of the effect of varying the third factor. Table 10 shows the relative effect of each factor.

VARIATION OF EVAPORATION IN THE UNITED STATES

Most of the records of evaporation were taken in the western part of the United States, comparatively few being available east of the Mississippi River. These records indicate in a general way, however, the variation in the United States.

The area of lowest evaporation is the Great Lakes region, where it ranges from 15 to 20 in. per year. East of the Mississippi River the evaporation increases from 20 in. in Maine to 43 in. at Birmingham, Ala., and then decreases slightly toward the Gulf Coast, with its greater humidity.

West of the Great Lakes the evaporation increases to 40 in. in the Upper Missouri River Basin. Southwest of the Missouri River, it gradually increases to 70 in. in Southwestern Texas and Southeastern New Mexico.

In the Rocky Mountain region, the evaporation depends largely upon temperature, which decreases with an increase in elevation. As an example of this fact, the records in Table 11 are cited.

As few records are available at the higher elevations, it is impossible to estimate the variation in evaporation in the Rocky Mountain region.

In the inter-mountain region, between the Rockies and the Sierra Nevada, the evaporation ranges from 38 in. in Northern Nevada to 60 in. in Southern Nevada and Arizona.

In the arid section of Washington and Oregon, comprising chiefly the region east of the Coast Range, evaporation ranges from 40 to 50 in. In the western half of Washington, the evaporation is generally less than 25 in., the lowest being at Lake Kachess, with a rate of 20.15 in. In Western Oregon, it is between 30 and 40 in.

In California, the rate of evaporation depends largely upon the elevation of the station. In the Sierra Nevada it ranges from 32 in. at Lake Tahoe to 62 in. in the southern part of the State. Throughout the remainder of California it ranges from 38 to 57 in., except in Imperial Valley, where an extreme of 97.10 in. has been recorded near Salton Sea, in the center of the valley.

STANDARD EQUIPMENT FOR EVAPORATION STATIONS

FINAL REPORT OF SUB-COMMITTEE ON EVAPORATION OF THE SPECIAL COMMITTEE ON IRRIGRATION HYDRAULICS

The recommendations of the Special Committee on Irrigation Hydraulics regarding standard equipment at evaporation stations, operated primarily to determine the evaporation from large water surfaces in the immediate neighborhood, are set forth as follows.

PANS

Two or more pans are highly desirable. If only one is feasible, the Class *A* land pan is preferred. If more than one is justified, the order of preference is as follows:

(*a*) United States Weather Bureau Standard Class *A* evaporation (land) pan. (A round land pan; 4 ft in diameter and 10 in. deep; of 22-gauge galvanized iron, without paint; supported on grillage; bottom of pan is 6 in. above ground surface. Details of set-up and procedure may be found in "Instructions for Installation and Operation of Class *A* Evaporation Stations."[23])

(*b*) Modified Colorado "buried" pan. (A square land pan; 3 ft on side; 18 in. depth; sunk in ground to within 4 in. of top; made of 18-gauge galvanized iron, without paint.)

(*c*) United States Geological Survey floating pan. (A square floating pan; same dimensions and material as in Preference (*b*); supported by two cylindrical metal floats, each 9 in. in diameter and 42 in. long; tank floating with 3 in. of its rim above the water surface.)

ESSENTIAL EQUIPMENT

Two items of equipment may be considered essential, namely:

One gauge for measuring evaporation.
One standard Weather Bureau rain gauge.

AUXILIARY EQUIPMENT

The following auxiliary equipment is listed in order of importance:

(*a*) One anemometer for recording wind velocities.

(*b*) One set of maximum-and-minimum thermometers, for air temperatures, housed in the standard instrument shelter of the U. S. Weather Bureau.

(*c*) One set of maximum-and-minimum thermometers for water temperatures.

(*d*) One sling psychrometer, to determine the relative humidity of air.

---

[23] *Bulletin* 559, U. S. Weather Bureau, *Circular L*, Instrument Div.

Alternate Equipment.—The following equipment may be substituted under the conditions stated:

(*b′*) Alternate to (*b*); one ordinary thermometer for air temperatures. Where readings can be taken at 12-hr intervals.

(*c′*) Alternate to (*c*); one ordinary thermometer for water temperatures. Where readings can be taken at 12-hr intervals.

(*b″*) Alternate to (*b*) or (*b′*); one thermograph for continuous record of air temperatures.

(*d′*) Alternate to (*d*); one recording hair-hygrometer for continuous record of humidity.

PAN COEFFICIENTS

Greater depth of water is evaporated from pans than from reservoir surfaces; hence, a coefficient is necessary to convert pan evaporation to the equivalent evaporation from a reservoir. Table 12 gives type of pan, recommended coefficient, and observed range of this coefficient.

TABLE 12.—RECOMMENDED COEFFICIENTS AND OBSERVED RANGE

Type of pan	Coefficient	Reasonable range of coefficient
(*a*) Class *A* land pan	0.70	0.60 to 0.82
(*b*) Modified Colorado "buried" pan	0.78	0.75 to 0.86
(*c*) U. S. Geological Survey floating pan	0.80	0.70 to 0.82

REASONS FOR SELECTION OF CLASS *A* LAND PAN AS STANDARD

The first selection must be made as between land pans and floating pans. The Sub-Committee reports two arguments in favor and four against the use of floating pans.

In favor of floating pans are the following:

(1) The amount of evaporation from the pan more nearly approximates that from the surrounding water; that is, a coefficient nearer 1.00 can be used.

(2) In controversial matters, the observations on a floating pan would be more acceptable to many engineers than those from a land pan.

Against a floating pan are the following:

(1) The ever-present possibility of the pan shipping water from the reservoir or losing water due to pitching of waves.

(2) A question as to the effect of measures to prevent shipping or loss of water. The same measure that retards gain or loss of water may set up a condition that increases or diminishes the actual evaporation loss in the pan, compared with that in the reservoir.

(3) Comparative difficulty of access may lead to poor attendance and to "desk readings."

(4) In controversial matters, records are difficult of unquestionable proof.

The items against the floating pan were determined to outweigh those in its favor so the land pan was preferred. The specific reasons are as follows: The U. S. Weather Bureau Standard Class *A* evaporation pan is selected as first choice because it has more features in its favor and fewer unsatisfactory ones than any other type of pan now known or thought obtainable by new design. It does not approach the ideal. Other pans excel it in certain respects, but are far behind it in others.

A summary for and against the U. S. Weather Bureau, Class *A* pan is as follows:

The advantages are:

(1) More data on this pan are available for comparison than on any other particular type of pan.

(2) The coefficient has been found to be about the same for this pan in comparison with large water surfaces in many locations and under many conditions.

(3) It is easy of access for observations.

(4) It is not subject to uncertainty due to inward or outward wash of water as is the case for a floating pan.

(5) It is raised above reasonable drift of dirt, débris, and snow.

(6) It is reasonable in cost of installation.

The disadvantages are:

(1) The coefficient is considerably less than unity; that is, the rate of evaporation is much greater from the pan than from a reservoir surface.

(2) For the data available, coefficients for certain months vary greatly from those for other months. This inconsistency, however, is true for all types of pans thus far studied.

By Sub-Committee on Evaporation,

Fred C. Scobey, *Chairman,*
Ivan E. Houk,
R. L. Parshall,
Carl Rohwer, *Co-Operating Member.*

June 18, 1932.

DISCUSSION

Ralph R. Randell,[24] M. Am. Soc. C. E. (by letter).—Wind, temperature, and humidity are the only factors the variations of which produce effects on reservoir evaporation sufficiently large to be important in most water supply problems. Therefore, if any collection of true reservoir evaporation data is properly adjusted to a given value of one of these three factors, the adjusted data should plot approximately consistently against the other two factors as co-ordinates.

The writer has investigated considerably, although not exhaustively, the question of whether, and to what extent, the annual evaporation data given in Table 8, of Mr. Follansbee's paper, meet this test. The tabulated annual evaporations were adjusted to fixed values of one or another of the three principal influencing factors on the basis of rational and widely held concepts of the effect of the factor upon evaporation. The annual rates of evaporation, as so adjusted, fail to plot even approximately consistently against the other two influencing factors as co-ordinates.

This failure of the adjusted figures to plot consistently raises a doubt in the writer's mind as to the approximate correctness of the data given in Table 8, and of the pan coefficients on which they are partly based.

Possibly, in the light of their intimate familiarity with the work, the authors, or the members of the Committee or Sub-Committee, may be able to devise an adjustment which will give results that plot consistently. It is earnestly hoped that they will attempt to do so, and will report thereon fully. This seems desirable for two purposes: First, to indicate what degree of accuracy and reliability the data possess; and, second, to put the data in such a form that they can be applied and used most intelligently and conveniently.

It is suggested that, first, all the yearly evaporation rates be adjusted to a common basis—as, for example, to a basis of 60% humidity, or a wind velocity of 4 miles per hr—and that the method of making the adjustment be stated. The adjusted evaporation rates should then be plotted against the two other principal evaporation-influencing factors as co-ordinates, the value of each adjusted rate, in inches per annum, being shown at the plotted point on the graph in small figures. Finally, generalized curves representing yearly evaporation rates of 10 in., 20 in., 30 in., etc., should be added.

Such a graph will show what degree of consistency the data possess, and, together with the adjustment formula on which they are based, will give the best obtainable approximation of the annual rate of reservoir evaporation corresponding to any given average values of wind, temperature, and humidity. Even if the given data plot somewhat erratically, the graph, nevertheless, may be of value in suggesting changes—either in the coefficients, the methods of adjustment, or otherwise—which will bring the data into better or more apparent consistency.

---

[24] Senior Engr., Federal Power Comm., Washington, D. C.

C. E. Grunsky,[25] Past-President, Am. Soc. C. E. (by letter).—It is with some reluctance that the writer undertakes to contribute his views on the determination of evaporation from large water surfaces to those expressed by the Sub-Committee on Evaporation of the Special Committee on Irrigation Hydraulics in its final report. He feels, nevertheless, that the profession has gone so far astray in its methods of evaporation observation in the past that the data on which the Sub-Committee's conclusions are based, should not be allowed to pass unchallenged, in order that what is dependable information may be segregated from that which is not dependable.

The writer does not agree with some of the conclusions of the Sub-Committee and will give his reasons briefly.

The Sub-Committee states that "if only one [pan] is feasible, the Class *A* land pan is preferred." The writer contends that this is a type of pan that should never have been brought into use, for the reason that its arrangement is such as to give maximum influence upon evaporation of sunshine and air movement. Even if a more or less consistent relation can be found between the record from such a pan and that from a near-by large water surface, it must be remembered that the heat due to sunshine is fed into the water from all parts of the pan that the sun reaches and that, consequently, the evaporation from an open water surface, wherever there is much sunshine, must be much less than the evaporation from the pan. This fact is apparent from the data cited, which indicate that generally such a pan will evaporate nearly 50% more water than a near-by open water surface will lose by evaporation.

By exposure to air on all sides and beneath it, maximum effect is given to air temperature changes. There is more warming and more cooling by contact of the air with the sides and bottom of the pan and with the surface of the water in the pan than if the water surface alone were exposed.

The correct type of standard land pan should preferably be circular, about 4 ft in diameter, with water about 12 to 15 in. deep, sunk into the ground to above the water level, and provided with an inverted V-shaped rider to shade the sides of the pan down to the ground on the outside and down to the water on the inside. The results of observations from a pan of this type will certainly establish relative rates of evaporation in different parts of the country much better than the Class *A* pan with its disturbing, constantly varying, sunshine factor.

The Sub-Committee recommends the use of the U. S. Geological Survey floating pan, but fails to state that no floating-pan record should be regarded as dependable and comparable with other records unless the water in the pan is at all times at a lower level than the water outside the pan. When this is not the case, heat is fed into the water of the pan by the sides, which capture heat from sunshine and air, and, in consequence, the pan record must exceed the actual evaporation from the water in which it floats, instead of closely approximating it. The Sub-Committee at least should add to its floating-pan recommendation the condition that the water within the pan at all times must be lower than the outside water. Undoubtedly, even the late Desmond

---

[25] Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif. Mr. Grunsky died on June 9, 1934.

Fitzgerald, Past-President and Hon. M. Am. Soc. C. E., failed to recognize the importance of this requirement, with the result that, at times, he found a difference of as much as a 10° F between the temperature of the water in his tanks and that of the surrounding water.

The experimental observations at the Salton Sea, part of which are reported by Mr. Rohwer in Table 3 (*c*), are to be used with extreme caution. The set of pans, for example, that were termed floating pans in the original record, was not of the correct type. They were purposely so suspended in the water that the water within the pans was 3 to 4 in. higher than the surrounding water. This fact was discovered by the writer some years after the experiments had been made, when he found that observation results would not agree with his own ideas as to evaporation rates in that locality. The only effect of the surrounding water at Salton Sea was to influence in some degree the water temperature in the pans. Unfortunately, these misleading records are being constantly quoted because the true circumstances are not known.

It may be assumed that nearly every floating pan of which there is record was improperly suspended. The endeavor has been to keep the top of the pan so far above the surrounding water that water from the outside will not splash in, and no regard has been had to the fact that when the inside water is above the surrounding water, all the heat fed into the sides of the pan above the water line goes into evaporation, which, instead of conforming to that of the outside water, is unduly accelerated. Here, too, therefore, a new start is desirable.

The writer calls attention in this connection to the statement by Mr. Rohwer that the Salton Sea pans referred to in Table 3 (*b*) were well immersed. They were not well immersed, and they should not be called floating pans. Referring to observations at Bakersfield ("General Comparisons: Land Pans and Floating Pans"), Mr. Rohwer decribes the floating pan as having the water on the inside 3 in. above that on the outside. The floating pan at Independence, likewise, is described as having had water at about 2 in. below its rim. The top of the pan was certainly higher than this above the outside water. Here, again, the record has but little value as a floating-pan record. Referring to the records from floating pans taken for the Canadian Pacific Railroad Company, Mr. Rohwer states that the water in the floating pans was kept slightly above the level of submergence. Even at the Fall River Mills, in California (see Table 2(*g*)), the writer some years ago found the water in the floating pan slightly above the outside water. Consequently here, too, there was undoubtedly slightly more evaporation from the pan than from the surrounding water.

As late as 1930, under expert direction, floating pans were placed in Suisun Bay, California, for a determination of evaporation in connection with studies for a salt-water barrier. The writer called attention to the fact that these were insufficiently immersed and that heat from the sides was being fed into the water of the pan, thus accelerating evaporation. At his suggestion, a comparison with a properly arranged floating pan was made. Although this comparison covered only the two cool months of October and

November, nevertheless it showed that the loss from the pan that had its water above the level of the outside water was 10% greater than the loss from a correctly arranged floating pan.

The writer makes the plea that the Sub-Committee revise its report; that the Type *A* pan be condemned; that the U. S. Weather Bureau be urged to make a new start, in the matter of evaporation observations, with land pans sunk in the ground, with the sides shaded, and with floating pans that have the inside water at all times below the outside water. It is only thus that results may be hoped for, which will stand comparison and which will help to establish some usable relation between meteorological conditions and the total evaporation from large open water surfaces in such periods of time as a month or a year.[26]

CHARLES H. LEE,[27] M. AM. SOC. C. E. (by letter).—The Special Committee on Irrigation Hydraulics is to be congratulated upon its accomplishment in producing a study of evaporation which is of practical value to the hydraulic engineer. Its selection of the U. S. Weather Bureau Class *A* land pan as a standard is thoroughly justified by all the facts. The writer concurs in this selection on the basis of his own experience with various types of pans, especially during the five years, 1928 to 1932. The findings of the Committee regarding the coefficient to be applied to the so-called U. S. Geological Survey floating pan are at variance with the view previously held by many, including the writer, that evaporation observed in such a pan closely approximates that from the surrounding reservoir or lake surface. The experimental results, however, would seem to support the coefficient of 0.80 adopted by the Committee.

S. T. HARDING,[28] M AM. SOC. C. E. (by letter).—This Symposium brings together much information that will be helpful to engineers having to do with work in which evaporation from water surfaces may be involved. The presentation of available records obtained from various types of pans and their relationship to the evaporation from large water surfaces furnishes a guide for the interpretation of existing data. The recommendations regarding standard pans for use in future observations will enable many of the variations of past observations to be avoided.

Measurement of evaporation presents many difficulties. This is particularly true of floating pans where, if the pan is placed far enough from the shore to secure conditions of exposure that are representative of the larger water surface, it is difficult to secure freedom from wave splashing without in turn affecting the exposure. Unforeseen conditions may arise which are difficult to overcome. In the writer's floating-pan records on Buena Vista Lake, which are quoted in the Symposium, inconsistencies occurred in the observations for the earlier months which could not be explained until the observer chanced to see pelicans using the pan as a bath-tub. It was necessary to place a coarse wire screen above the pan to prevent this loss of water.

E., State Engr. of California, 1886, p. 379; *Engineering News*, Vol. 60, August 13, 1908, pp. 163-166; *Bulletin No. 100*, U. S. Dept. of Agriculture, p. 323; *Monthly Weather Review*, 1908 and 1910; and, "Evaporation from Lakes and Reservoirs,' by the late C. E. Grunsky, Past-President, Am. Soc. C. E., *Monthly Weather Review*, Vol. 60, January, 1932.

[27] Cons. Hydr. Engr., San Francisco, Calif.

[28] Prof., Irrig., Univ. of California, Berkeley, Calif.

While the material in the Symposium covers the effect of type and size of pan thoroughly, there are other factors which affect the relationship of the evaporation from pans and from large water surfaces which may make as much difference as variations in the size of pan. This is illustrated by the two following cases.

In describing[29] the work of the U. S. Geological Survey in the Escalante Valley, Utah, Mr. W. N. White gives the results of observations of pans 20 in. and 12 ft in diameter. Two of the smaller pans were used. In one set of observations the two smaller pans floated in the 12-ft pan, being set in the direction of the prevailing wind; in the other set, they were set in the ground adjacent to the 12-ft tank in the same directions. From May to August, 1927, the 12-ft pans had an evaporation of 23.34 in., the windward floating pan, 28.44 in., and the leeward floating pan, 24.49 in. For a period in August and September, 1927, the 12-ft pan had an evaporation of 7.89 in., the small sunken land pan on the windward side, 10.15 in., and the similar land pan on the leeward side, 8.76 in. In the case of the small floating pans the evaporation on the windward pan was 16% greater than that for the leeward pan; for the two sunken land pans, the evaporation on the windward pan exceeded that on the leeward pan by the same average percentage.

In Table 8 of Mr. Follansbee's paper the mean evaporation from April to September from a reservoir surface at Fallon, Nev., is given as 44.50 in., based on records from 1908 to 1930, with a pan having a coefficient of 0.94. This is the pan at the Fallon Experiment Station of the U. S. Department of Agriculture. Observations were begun in 1908 and were continued to 1920, when the station was closed until 1922, when it was re-opened. The evaporation observations have been continued to date (1933). Recently, while making some studies of evaporation in this area, the writer noted that the results since 1922 showed smaller amounts of evaporation than those for the earlier period. For the months from April to September, for the 12 years, from 1908 to 1919, the evaporation from the pan varied from 47.13 to 55.04 in., with a mean of 51.64 in. For the 10 years, from 1923 to 1932, the evaporation for the same months varied from 36.47 to 44.97 in., with a mean of 39.45 in. The mean for the earlier period exceeded that for the latter period by 30%; the evaporation in the maximum year in the later period was only 95% of the evaporation in the minimum year of the earlier period.

Mr. E. W. Knight, in charge of the Experiment Station, states that when the station was re-opened in 1922, the evaporation pan was moved from a small hill in the farmed area of the station to a level area near on irrigated field. Records of wind movement obtained adjacent to the pan show an average reduction in wind velocity of about 25% at the site used since 1922. There has been little difference in mean temperature for these months. While there are no records on large water areas in this vicinity covering both parts of this period, there is no reason to expect that records would have shown any essential differences in actual evaporation from such large water surfaces in the earlier and later years.

---

[29] *Water Supply Paper 659-A,* U. S. Geological Survey.

In the observations in Escalante Valley, a water surface 12 ft in diameter set between two small pans resulted in differences in evaporation of 16% due to differences in humidity or other factors. In the observations at Fallon moving the evaporation pan from a small hill about 10 ft to a level area near an irrigated field, but still within the same 160-acre tract and subject to the same general climatic conditions, resulted in a 30% difference in evaporation. These results indicate that the conditions of exposure may be a larger factor in the relationship between the evaporation from pans and large water surfaces, than the factors due to the size of the pan.

L. STANDISH HALL,[30] ASSOC. M. AM. SOC. C. E. (by letter).—A great volume of data has been gathered for this Symposium. In a strict sense, the evaporation from reservoir surfaces is still a matter of question. The coefficients for some of the types of pans in use show a wide range, and although reasonable values have been determined for reducing annual pan evaporation to equivalent reservoir-surface evaporation, little is known of the ratio to be applied in individual months.

The engineers of the East Bay Municipal Utility District (and its predecessor, the East Bay Water Company) have made comparisons of evaporation from different types of pans since 1921. In that year four pans were installed at the San Pablo Reservoir, near Oakland, Calif. All the pans were 3 ft square and 1.5 ft deep, two being Type 2 pans and two being Type 4 pans. One land and one floating pan were located near the dam, and another pair near the outlet tower about 7 000 ft up stream from the dam. The floating pans were anchored near the shore, and the land pans were kept about 10 to 20 ft in elevation above the reservoir level. Rain gauges were maintained near the land pans. The pans were moved at various times according to the elevation of the water surface in the reservoir, but were kept in the same relative positions. Due to an error in attaching the floats to the reservoir pans, the water level in the pans stood between $\frac{3}{4}$ in. and 1 in. higher than the outside water surface.

In 1930, a new evaporation station was installed at this reservoir near the dam. The land station consisted of one Type 2 pan and one Type 3 pan, with anemometer, maximum and minimum air thermometer, and standard rain gauge. This station was located on top of the dam. The reservoir station, consisting of one Type 4 floating pan and a standard rain gauge, was located at the same place as the old floating pan near the dam.

At Upper San Leandro Reservoir, 12 miles southeast of San Pablo Reservoir, a land pan (Type 3) and a floating pan (Type 4) were maintained near the dam from 1925 to 1929. The record for this period is fragmentary. In 1930, a new station was installed near the outlet tower. This station was a duplicate of that placed at San Pablo in the same year.

---

[30] Chf. Hydrographer, East Bay Municipal Utility Dist., Oakland, Calif.

At Pardee Reservoir, near Valley Springs, Calif., about 80 miles east of Oakland, an evaporation station was installed in 1930. The equipment was similar to that at San Pablo Reservoir, with the exception that a Class *A* Weather Bureau pan was included with the pans at the land station.

The available data, reduced to monthly averages for each of the aforementioned stations, is included in Table 13.

A comparison of the ratio of evaporation for the various types of pans shows a marked difference between the relative evaporation from land pans and floating pans between the winter and summer months. Even as between two land pans of different types the ratio is not constant throughout the year. Evaporation records from stations other than those at the District's reservoirs, although they show different values of the ratio of evaporation from pans of the several types, do not indicate the marked difference between summer and winter evaporation. In many localities the maintenance of evaporation stations during the winter months is impossible because of freezing temperatures, so that a complete annual comparison is not available.

On the basis of these data, the writer cannot agree with the conclusion of the Sub-Committee that the Class *A* Weather Bureau pan (Type 1) is preferable for an evaporation station "operated primarily to determine the evaporation from large water surfaces in the immediate neighborhood." The test at Fort Collins, Colo., on the 85-ft reservoir, shows that the pan floating in the reservoir followed the reservoir evaporation month by month more closely than the land pans. The Class *A* pan showed the greatest range of coefficient. The evaporation varies with wind, temperature, and humidity, and in a reservoir the temperature of the water may differ greatly from that in a small land pan. With regard to the East Bay District's reservoirs, the results obtained from land pans and water pans can be easily explained. The reservoirs are relatively deep and, in the winter months, the water temperature in the reservoir is greater than in the land pans, resulting in relatively greater evaporation. In the summer months the converse is true, with the result of relatively less evaporation.

Judging from the results at some of the other stations, where comparisons of land pans and water pans are available, similar conditions did not prevail. One difficulty in the comparison of land pans and floating pans is that wind conditions may not be the same at both pans, even if the pans are relatively close to each other. A wide range in evaporation can be seen in the results at San Pablo Reservoir since 1930 (Table 13(*b*)). The land pans on top of the dam are exposed to the full sweep of the prevailing winds. The floating pan is sheltered from the wind by the dam, and has materially less evaporation. Another difficulty in the comparison of floating-pan records is that a large majority of the floating pans are not completely immersed, but have the water level in the pan at a higher level than in the surrounding reservoir. The floating pan near the dam at San Pablo Reservoir was not completely immersed from 1921 to 1929, but after 1930 the water level in a pan at the same location was about $\frac{1}{4}$ in. below the water level in the reservoir. The mean annual pan evaporation for the first period was 47.8 in., and

* Square.

for the second period, 40.9 in. Some of this difference may have been due to climatic variation and some to the inflow of cold water from Pardee Reservoir during the latter period. It does not seem probable that the entire difference was due to pan immersion.

Buried pans may be subject to varying temperature control. When buried in clay or adobe soil, the shrinkage of the earth around the pan during the summer months may result in the sides being exposed to the air. Earth may be removed from around the pan by wind or erosion, exposing the sides below the water level. Pans buried near the water edge of a reservoir or in marshy ground may, in effect, simulate a floating pan. This condition applies to the buried pan at Los Griegos, N. Mex. According to the data[31] originally presented, the ground-water was above the bottom of this pan at all times. Judging from the location of the pans in Fig. 3, a similar condition may have existed relative to the buried pans at the East Park Reservoir, in California.

The Class *A* Weather Bureau pan, being placed above ground, is not subject to the varying temperature control which may effect buried or floating pans. The results, therefore, may be more consistent although the recorded evaporation does not necessarily follow that from an adjacent reservoir. In cases where the pans cannot be given adequate supervision, this pan has many of the advantages set forth by the Sub-Committee, to recommend it.

To the Sub-Committee's recommendation that two or more pans are highly desirable, the writer would add, that if two pans are used, one should be a land pan and one a floating pan. In windy locations, the use of one pan may be misleading. For example, at the San Pablo Reservoir, the writer has used the evaporation of the floating pan since 1930, without correction, as representing most closely the evaporation from the reservoir surface.

---

[31] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 984.

Due to the difficulty of maintaining floating pans in a large reservoir, the writer believes that a more accurate comparison of land pans and floating pans could be made by floating the water pan in a tank adjacent to the land pan. For a Type 4 pan, such a tank could be 8 ft in diameter and 3 ft in depth. The tank should be buried in the ground, and an effort made to keep the tank temperature as close as possible to the temperature of the surface water in the reservoir.

The experiments[2] made by the late R. B. Sleight, Assoc. M. Am. Soc. C. E., appear to be very trustworthy. The floating pans, however, cannot be directly compared with the land pans, due to the fact that the pans were not at the same location, as mentioned by Mr. Rohwer. The writer, by comparison of results between land pans and floating pans at Denver, Colo., with the results obtained at Salt Creek Bridge, in California, has revised the coefficients for floating pans obtained by Sleight, as shown in Table 14.

In other instances, in addition to the one just cited, the writer could not agree with the values of the coefficients determined in various parts of the Symposium. The coefficients for the types of pans in most general use, as well as the mean for each type have been assembled in Table 16, and in Table 15 these results are compared with the coefficients determined by

Messrs. Sleight, Rohwer, Follansbee, and the Sub-Committee. The coefficient of 0.92 for the 6-ft ground pan was determined from a longer record on the pan 3 ft deep at Denver, and is believed to be more representative than the coefficient of 0.94 from the short record on the pan of standard depth.

* 1916 to 1917; indirect method. † 1917; indirect method. ‡ 1910. § Indirect method. ‖ 1930 to 1932. ¶ 1921 to 1929; average of two pans; indirect method.

The comparisons of the Type 3 and Type 4 pans indicate that the evaporation is greater from the floating pan. The results from the East Bay District's measurements are very consistent and show 8% greater evaporation from the floating pan. Based on these records alone, the coefficients would be: Type 3, 0.85; and Type 4, 0.79. The coefficient for the Type 5 pan appears to be 0.88.

In selecting a pan to determine reservoir evaporation, the writer would reverse the selection recommended by the Sub-Committee and would give preference to the pans in the following order: (*a*) Floating pan, with preference to the U. S. Geological Survey pan; (*b*) buried pan, with preference to the Colorado pan, and then to the 4-ft or 6-ft circular pan; and (*c*) U. S. Weather Bureau Class *A* pan.

ADOLPHO SANTOS, JR.,[32] JUN. AM. SOC. C. E. (by letter).—The primary object of the Symposium "has been to find a suitable set of coefficients * * * to the end that evaporation from a large water surface could be expressed in terms of that from the various types of pans in use." In the light of certain researches and experiments conducted on the subject of evaporation from large water surfaces, it seems that the appropriateness of the method of attack chosen for obtaining such a suitable set of coefficients is not beyond criticism.

The researches and experiments referred to, made principally at the Scripps Institution of Oceanography and at the California Institute of Technology, would appear to indicate that the method adopted by the authors for estimating evaporation from reservoirs on the basis of pan observations yields results of debatable precision. For a proper solution of the problem, the adoption of the point of view and technique originated and advocated by Messrs. G. F. McEwen, N. W. Cummings, I. S. Bowen, B. Richardson, and C. Montgomery, is essential. It is to be regretted that not even passing mention is made by the authors of the work of these men[33] who have succeeded in placing the physics of evaporation on a firm foundation.

Messrs. Cummings and Richardson have stated[34] that:

> "Evaporation can be determined by the aid of the first law of thermodynamics in such a way that wind velocity need not enter the calculation. Air temperature and humidity enter only as terms in a correction which can have a relatively small average value under typical conditions."

As long as this fact is not fully realized and made use of by engineers, and as long as pans of various types and sizes, under varying conditions of exposure, continue to be used, the ratio between evaporation from pans and evaporation from a large open water surface will remain a matter of controversy and dispute, with small gain in factual knowledge of general applicability. As long as empirical methods are used, the "laws," "constants," and "coefficients" resulting from even elaborate experiments must of necessity remain of local and restricted value only.

E., Vol. 95 (1931), pp. 996 *et seq.*

[34] "Evaporation from Lakes", by N. W. Cummings and B. Richardson, *Physical Review*, Vol. 30 (1927), pp. 527–534.

For example, in water supply problems, it is generally held that wind velocity, temperature, and humidity are the only factors that produce effects on reservoir evaporation sufficiently large to be important. It happens, however, that this very natural and common view was not supported by an extensive statistical analysis made by Dr. Cummings for the purpose of isolating the effects of the various factors influencing evaporation. In fact, a very weak correlation was indicated between evaporation and humidity and between evaporation and wind.[35] This led Dr. Cummings to attack the problem from the standpoint of the first law of thermodynamics and to formulate the fundamental qualitative principle of evaporation, as follows:

> "Any change in wind or humidity is always accompanied by a change in lake temperature which partially neutralizes the direct effect on the evaporation rate to be expected from the original change in atmospheric conditions, if the insolation remains constant."

It would appear, therefore, that if one should adjust evaporation rates, by means of the empirical formulas in common use, to fixed values of one or another of the three factors—wind, temperature, and humidity—it will be found that after adjustment the data do not plot consistently against the other two factors as co-ordinates.

When the water in a floating pan is kept above the level of submergence, the rate of evaporation from the pan will exceed that of the surrounding water. The writer is not certain, however, that by simply keeping the water in the pan at all times at a lower level than that of the water in which it floats the two rates will become identical. The first question that naturally arises is: How much lower? Is it not conceivable that if the level is low enough the evaporation from the pan will be less than that from the reservoir?

The writer earnestly hopes that the Sub-Committee will adopt the standard procedure and technique advanced by Dr. McEwen, and his co-workers. Like most primary standards it is difficult to apply. By this means, however, a simpler and more readily applicable method could be developed for determining evaporation from reservoirs with the degree of accuracy sufficient for engineering uses.

The words of Dr. Cummings in discussing Professor Richardson's paper,[36] with slight modification, may be applied to the question being considered:

> "It may be some time before the true value [of the procedure based on the first law of thermodynamics] is fully appreciated, because economic pressure has not yet compelled the abandonment of unnecessary complications in estimating evaporation from lakes and reservoirs."

[35] "Relation Between Evaporation and Humidity", by N. W. Cummings, *Bulletin No. 68*, National Research Council (1929), pp. 47–56.

[36] *Transactions*, Am. Soc. C. E., Vol 95 (1931), p. 1017.

John W. Pritchett,[37] Assoc. M. Am. Soc. C. E. (by letter).—While this Symposium brings together many evaporation data not heretofore collected in one publication, it is also noted that many evaporation records in Texas, covering long continuous periods, are not disclosed. This is doubtless true of evaporation data covering other sections of the United States. There are many evaporation records that have never been published, which would be of much value to the profession. The U. S. Weather Bureau would be a good agency to handle such work if allowed the necessary money.

Evaporation records beginning in 1915 or 1916 are being taken at eleven Texas Agricultural Experiment Stations. Records taken by the Bureau of Agricultural Engineering, in co-operation with the Texas Board of Water Engineers, at Mercedes, in the Lower Rio Grande Valley, are valuable in that comparison may be made of the evaporation from pans of different sizes and under varying climatological conditions for complete yearly periods. The land tanks were 1, 2, and 3 ft in diameter, and the floating tank was 2 ft in diameter.

Many of the Texas data are all-year records and on that account would be particularly valuable in carrying on evaporation studies. The San Antonio Field Station, Bureau of Plant Industry, U. S. Department of Agriculture, has an evaporation and temperature record beginning January, 1907. This is a complete 26-yr. record for a land pan (Type 2), 6 ft in diameter.

Table 5(*b*) shows a comparison of Pan (1) and Pan (4) at Austin, Tex. This is known as the Hill's Ranch Station, and is about five miles southeast of Austin. It was established by the Water Resources Branch of the U. S. Geological Survey in co-operation with the State Board of Water Engineers and with the U. S. Weather Bureau. The records were taken under the direction of the District Engineers of the U. S. Geological Survey, and the computations were made by the Weather Bureau.[38]

This station was established on March 9, 1916. It is 475 ft above sea level, at Latitude 30° 14′ N, and is located about 1 000 ft from the ranch house. Observations are taken daily at 8:00 A. M., 90th Meridian time.

According to the U. S. Geological Survey,[39] the topography is rolling to the north and east and rough to the west and south, with a gradual slope to the Colorado River. In the immediate vicinity of the pan the slope is approximately 30 ft per mile. The reservoir is 30 by 200 ft, instead of 20 by 150 ft, as reported in the Appendix to Mr. Rohwer's paper, and the galvanized iron floating pan (36 in. square and 13 in. deep) is located 30 ft east of the land pan. It is freely exposed to the rays of the sun at all daylight hours.

This is probably one of the most complete records that may be found from which to determine the relationship between the evaporation from pans of Type (1) and Type (4). While the published records frequently show days missing or estimated records, the original records are practically complete. In cold weather when the pans were frozen over, the record was omitted in the publication and noted as days missing. The 14-yr. monthly record similar to Table 5, of Mr. Rohwer's paper, was tabulated by the writer, using all records, and using 32° F for the water surface temperatures when the records showed frozen water surface.

---

[37] Engr., State Board of Water Engrs., Austin, Tex.

[38] "Climatological Data, Texas Section," U. S. Weather Bureau, December, 1916.

[39] *Water Supply Paper No. 438*, U. S. Geological Survey, p. 31.

Comparing these results (not published) the writer has found that there is remarkably little difference between them and the data in Table 5. This would seem to indicate that a few years of evaporation record at a given station may suffice for all practical purposes.

The writer agrees with Mr. Rohwer and with the Sub-Committee that from the standpoint of making comparisons with known data on evaporation, the Class *A* Land Pan of the U. S. Weather Bureau (Pan (1)), is probably best adapted to the study of evaporation from water surfaces, because a large number of these pans have been installed in the United States, and many observational data obtained under similar conditions with a uniform procedure, are available from them.

In Table 10, Mr. Follansbee attempts to show the effects of factors influencing evaporation. In Table 10(*a*), showing the effect of temperature, the Washington, D. C., data are compared with the Austin, Tex., data. The 14-yr. record of the Austin Station shows a mean temperature of 67° F compared to 68° F, as shown in the table. The wind velocity at the pan, in miles per hour, is 2.1 compared to 2.0, as shown in the table. The relative humidity is 66 compared to 68. The evaporation for the 14-year record is 45.6 for both Pan (1) and Pan (4), applying a factor of 0.69 to the Pan (1) records and a factor of 0.90 to those of Pan (4).

In comparing stations of approximately the same mean annual temperature, in order to show the effect of wind velocity and of relative humidity on evaporation, it appears to the writer that it would be necessary to know that the stations had not only the same mean annual temperature, but also the same range of temperature.

In establishing the coefficients to be applied to the different types of evaporation pans, in order to reduce the evaporation to the open-water equivalent, it is suggested that a more accurate determination might be made by finding coefficients that would apply to certain temperatures or ranges of temperature. Determining coefficients for individual months would have somewhat the same effect.

Various formulas have been derived from which evaporation estimates may be made that are sufficiently accurate for many practical purposes. The application of such formulas may soon be found to be a more practical manner of estimating evaporation, rather than basing such formulas on evaporation-pan records. Evaporation observations would then only be necessary for scientific purposes, or where extreme accuracy could be attained in obtaining climatological data.

IVAN E. HOUK,[40] M. AM. SOC. C. E. (by letter).—The papers by Messrs. Rohwer and Follansbee furnish a long needed digest of available evaporation data. Mr. Rohwer's paper brings together valuable information regarding comparative evaporation rates observed at different types of pans, and their relations to actual evaporation losses from large reservoir surfaces. Mr. Follansbee's paper presents comprehensive and valuable compilations of pan evaporation data reduced to equivalent reservoir evaporation.

---

[40] Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

As regards the ratios of pan evaporation to reservoir evaporation, it is not surprising that there should be some differences between results obtained at different locations. Considering the varying meteorological conditions throughout the country it would not be logical to assume that the ratio of the evaporation rate at any given pan to the evaporation loss from a large reservoir surface in the vicinity of the pan should have the same value in all localities. However, considerable porportions of the differences shown in Mr. Rohwer's tabulations are probably due to incidental errors of observations and lack of strictly comparable environment at the different places where the investigations were conducted.

The writer would not expect the data on pan ratios secured at the Stonyford, Calif., installations (Fig. 3), to be susceptible of general application, because of the proximity of the pans to each other and to the shore of the reservoir. The slightest offshore or onshore breeze must have produced essentially the same vapor pressure in the air immediately over the different pan surfaces; so that the only factor causing differences in evaporation rates at the different pans must have been the temperature of the water within the pans. Moreover, ratios of reservoir evaporation to pan evaporation at Stonyford must have been affected materially by the prevailing wind direction. In such an installation prevailing offshore breezes would mean definitely lower ratios of reservoir evaporation to pan evaporation than would be the case if onshore breezes predominated.

In the Stonyford installation the writer would expect the evaporation rate at the floating pan to be essentially the same as at the sunken land pans. Somewhat different ratios of reservoir evaporation to pan evaporation undoubtedly would have been obtained at the different pans if the floating pan had been in the center of the lake and the land pans entirely away from the reservoir. In other words the grouping of the pans near the shore of the lake tended to eliminate one of the variable factors that affect the rate of evaporation. Consequently, engineers cannot apply, blindly, ratios determined at such installations to land pan measurements made in a desert country, entirely away from any large body of water. Such ratios can only be used in the case of pan measurements near large lakes or reservoirs, where the relative humidity above the pan is substantially the same as over the larger water areas.

Mr. Follansbee's paper supplies a wealth of information regarding estimated reservoir evaporation based on pan measurements in different sections of the United States. His tabulations can be used in preliminary investigations of proposed storage projects, selecting the stations most comparable as regards elevation, temperature, relative humidity, and wind velocity. The writer believes that Mr. Follansbee's calculated estimates of reservoir evaporation in Western United States are on the safe side in most cases;

that is, that they tend to be too high rather than too low, if in error at all. The reason for this belief is that in a few cases the pan measurements may have been made in regions where the relative humidity is definitely lower than that at the locations where the pan ratios were determined, and also definitely lower than the relative humidity that will occur in the vicinity of the pan after a large reservoir is constructed.

The Yuma (Citrus) Station, in Arizona, (Table 8 (*r*)) is an example of the aforementioned conditions. In this case the writer believes that the coefficient of 0.69 used to reduce Class *A* pan evaporation to reservoir evaporation is entirely too high. If a large reservoir was built at the location of the Yuma (Citrus) Station the relative humidity of the air above the reservoir surface probably would not be materially different from the relative humidity of the air above a large reservoir at the Yuma (Date Orchard) Station. Consequently, since the wind velocities and air temperatures are practically the same at the two stations, the evaporation rates at the two reservoirs would be essentially the same and the ratio of reservoir evaporation to past pan records at the Yuma (Citrus) Station would be much lower than 0.69. Meteorological conditions at the Yuma (Citrus) and the Yuma (Date Orchard) Stations and their effects on measured pan evaporation were discussed in a previous paper by the writer.[41]

In finally planning any important storage development, the engineer should consider carefully the meteorological conditions at the proposed reservoir site before and after construction and their relations to the meteorological conditions at the places where the pan ratios were determined, before adopting a definite value for the ratio of reservoir evaporation to pan evaporation. The engineer might also, profitably, consult Mr. Rohwer's excellent and comprehensive *Bulletin*[42] which gives the results of recent investigations by the U. S. Department of Agriculture at Fort Collins, Nebr., Logan, Utah, Imperial and Lake Tahoe, California, and Fort Collins, Victor, and Pike's Peak, Colo. In that *Bulletin* Mr. Rohwer not only showed conclusively that the Dalton law, proposed in 1802, constitutes a satisfactory theoretical basis for a practicable evaporation formula, but also developed such a formula from his extensive evaporation measurements and tested it in many different locations and at many different altitudes throughout the country.

In order to use the Rohwer formula in a given case it is necessary to know the altitude, wind velocity, relative humidity, and water surface temperature. Since the altitude is practically always known with a sufficient degree of accuracy, only three factors remain to be determined. Of these three, wind velocity has already been measured more or less extensively at meteorological stations maintained by the U. S. Weather Bureau; so that the principal additional data needed are values of relative humidity and water surface temperature in different sections of the country, both of which quantities are easily measured with relatively inexpensive equipment. Engineers interested in securing better evaporation data should encourage the measurement of relative humidity and water surface temperatures at lakes and reservoirs whenever possible, as well as the establishment of additional evaporation stations and the measurement of all pertinent meteorological conditions at such installations.

[41] "Evaporation on United States Reclamation Projects," by Ivan E. Houk, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), pp. 282–285.

[42] "Evaporation from Free Water Surfaces," by Carl Rohwer, Assoc. M. Am. Soc. C. E., *Technical Bulletin No. 271*, U. S. Dept. of Agriculture, Washington D. C., December, 1931.

R. I. MEEKER,[43] M. AM. SOC. C. E. (by letter).—Evaporation losses from reservoirs and river channels, in the Western United States, have become a matter of considerable importance to irrigation engineers, in recent years, due to interstate river problems and numerous proposed channel reservoirs of large capacity. Information and engineering data on evaporation from water surfaces were relatively meager before 1924.

In 1927, Ivan E. Houk, M. Am. Soc. C. E., brought together in compact form valuable information[44] now pertinent to engineering studies of river equalization. The Symposium on "Evaporation from Water Surfaces" is a fitting conclusion to the interest awakened in the profession by Mr. Houk's paper.

The contributions of Mr. Rohwer and of Mr. Follansbee represent extensive research, exacting compilation, and careful analytical study of an immense mass of records—State, regional, continental, and foreign. Table 8 in Mr. Follansbee's paper is a most valuable reference work because of its comprehensive character. Table 10 is most instructive, and forces one to study comparative values of evaporation from the factors presented.

The conclusion of the Sub-Committee, in favor of the Class *A* land pan as to desirability for evaporation records is sustained by the experience of the writer. No floating-pan records secured by him were ever satisfactory as to accuracy, due to indeterminate water gains or losses from wave action.

These papers on evaporation, supplemented by "Evaporation from Free Water Surfaces"[45], by Mr. Rohwer, will furnish a satisfactory library for years to come on that important subject.

CARL ROHWER,[46] ASSOC. M. AM. SOC. C. E., (by letter).—In preparing this paper the writer had no intention to minimize the importance of the work being done by Messrs. Richardson, Cummings, and McEwen on the relation between insolation and evaporation. It is generally conceded that, over a period of time, the quantity of water evaporated will depend on the insolation. There are several practical difficulties, however, which must be overcome before this method can be used for the determination of the evaporation losses from water surfaces and, until more information is available, the method cannot be used generally in evaluating the evaporation loss from a reservoir.

The mere fact that the evaporation data do not plot consistently when adjusted to a fixed value of one of the factors affecting evaporation, does not necessarily mean that the original data, or that the pan coefficients, are incorrect, as suggested by Mr. Randell. The apparent inconsistency in the data may be due to several causes: First, the method of adjusting them to a fixed value of one of the factors affecting the result may be in error; second, the meteorological data given may not have been taken at the evaporation pan; and, third, the meteorological data, although taken at the evaporation pan, may have been observed at such times that the means do not represent the true conditions. Any one or all three factors might cause inconsistencies in the plotted results.

[46] Associate Irrig. Engr., Colorado Experiment Station, Fort Collins, Colo.

The writer agrees with the statements of Mr. Grunsky concerning the evaporation from the U. S. Weather Bureau, Class *A* land pan. He admits also that the evaporation from a sunken circular pan provided with a shield to protect the exposed rim from sunshine would approach more nearly the evaporation from a large body of water. Records from the latter type of pan are not available, however. Although the evaporation from the Weather Bureau pan is much greater than that from a lake or reservoir, this type of pan has many advantages, as has been stated, and for these reasons it is recommended for use.

There is a noticeable lack of uniformity in the method of maintaining floating pans, which is, in part, the cause of the inconsistent results obtained from these pans. The data as to the setting of the floating pan for which evaporation records were reported by the writer, were given to acquaint the reader with the conditions under which the readings were taken and not with the intention of recommending the particular setting. As pointed out by the writer, the water in the U. S. Geological Survey floating pan should be maintained at the same level inside as outside.

Mr. Pritchett calls attention to additional records on evaporation from pans of different sizes, and states that the reservoir at Austin, Tex., is 30 by 200 ft, instead of 20 by 150 ft. It is the writer's understanding that the size of the reservoir varies with the rainfall and is at times even smaller than 20 by 150 ft.

The evaporation records submitted by Mr. Hall provide additional information as to the relation between the evaporation from floating pans and from other types. It is unfortunate that this information was not included in the writer's paper, as only a few records concerning the comparison between the evaporation from floating pans and land pans were obtained. The writer does not agree, however, with Mr. Hall's recommendations as to the types of pans to be used for the study of the evaporation from reservoirs. His own records (Table 13) show that the results obtained from the floating pans are more erratic than those from land pans.

The observations by the writer on the floating pan in the 85-ft reservoir at Fort Collins, Colo., were made under laboratory conditions where it was possible to measure the evaporation accurately and to observe whether water was splashing into or out of the pan. It is doubtful whether as consistent results would be obtained under field conditions. The land pans at Stonyford, Calif., were installed in damp sand, but the conditions were scarcely similar to those under which floating pans are exposed.

The ratios given by the writer in Table 6 are based on the available records, but they are not final. Whenever additional information on the evaporation from different types of pans becomes available the ratios given should be recomputed on the basis of all the data.

Mr. Houk calls attention to the effect of variation in the humidity near large bodies of water on the evaporation from pans. It is generally accepted that the air is damper near lakes and reservoirs; but the effect of the water on the evaporation is not as great as might be expected, for two reasons: (1) Because moist air is lighter than dry air, the moist air is rising continuously and being replaced by dryer air (but for this fact and the influence of the wind, the air near a lake or reservoir would soon become saturated); and (2) the rate of evaporation is proportional to the difference in vapor pressure between the water surface and the air above it. In arid sections (particularly in the summer), the vapor pressure of the water surface is much greater than the vapor pressure of the air, and, consequently, small changes in the vapor pressure of the air due to proximity to a large body of water have a relatively small effect on the rate of evaporation of pans near the lake or reservoir. This conclusion is supported by the observations in Table 6, Items Nos. 44 to 49, inclusive, which show that the correction factors for obtaining the reservoir equivalent are practically the same whether determined near a lake or away from the influence of a large body of water.

The observations reported by Professor Harding pertaining to the evaporation from small land and floating pans located on the leeward and windward sides of the 12-ft evaporation pan at Escalante, Utah, indicate that the evaporation is less on the lee side of the large pan. This may be due to the difference in humidity, but other factors, such as wind and temperature, may have some effect also. The effect of wind is clearly shown by Professor Harding by the observations on the pan at the Fallon Experiment Station. Wind is more likely to be the cause of differences in evaporation records than temperature or humidity. For this reason the pan should be exposed as nearly as possible to the same wind conditions as the reservoir for which the rate of evaporation is desired.

In conclusion, the writer would like to call attention to the fact that the ratios given in his paper are averages, usually covering several months, and are based on the total evaporation for the period and not on the average of the monthly ratios. For this reason the ratio for a particular month of the year may differ from the average for the period. This fact should be given consideration when computing monthly rates of evaporation, particularly for the winter months when the pan may be frozen while the reservoir still remains open.

Robert Follansbee,[47] M. Am. Soc. C. E. (by letter).—In publishing all available records of evaporation (the real purpose of the writer's paper) two courses were open: (1) To present the records as observed with the knowledge that, obviously, they were not comparable, owing to the various methods by which they were obtained, and thus could not give even an approximately true picture of the variation in evaporation due to variations in meteorological factors; or (2) with the aid of known comparisons to reduce all records to approximate reservoir surface evaporation which would be much more nearly comparable than the observed records and, at the same time, would present the factor used in each case, in order that the user of the records might easily deduce the originals and thus correct them by any factor he chose, based on additional information. The latter method was selected.

---

[47] Dist. Engr., U. S. Geological Survey, Denver, Colo.

In selecting the reservoir surface method the writer was well aware of the fact that in some instances the known reduction factors were probably subject to error, and that the resulting values would appear inconsistent when compared with the accompanying meteorological factors. One reason for these inconsistencies undoubtedly lies in the fact that these factors are not in every instance directly comparable. While an attempt was made to obtain exact information regarding them and the points at which they were observed, such attempt was not always successful. Particularly is this true of the foreign records presented in this closure. One of the greatest uncertainties is the mean value used for relative humidity. At only a very few stations are continuous records of relative humidity available, and the great majority rely on two or three readings per day, taken during the daylight hours. In the case of the Australian records (Table 17 (*g*)) one reading per day is taken. In some climates the error in computing the mean daily relative humidity from one, two, or (at regular U. S. Weather Bureau stations), three, readings per day may give the true daily mean within a few per cent., but in other climates considerable error may be introduced. Mr. Pritchett's discussion of the writer's comparison between the evaporation at Washington, D. C., and Austin, Tex., as given in Table 10, illustrates the variation in relative humidity at different hours of the day. Mr. Pritchett states that the relative humidity at Austin, as shown by a 14-yr record, is 82%, whereas the writer had given 68% in his record. From subsequent correspondence, it has been learned that the value of 82% was based on one reading per day at 8:00 A. M., whereas the Meteorological Observer at the University of Texas states that the mean for the day is about 66%, the method of arriving at the mean not being given. This value agrees closely with the 68% used by the writer.

Another uncertainty is the height above the ground at which the wind velocity is measured, and the exact exposure of the evaporation pan as compared with the point at which the wind velocity is measured. As an additional example of the effect of wind on the rate of evaporation two records at Singapore may be cited. The Water Engineer's Department maintains two similar evaporation pans not very far apart, the mean annual evaporation for the same period being 52.95 in. for one and 42.33 in. for the other. The explanation for this difference is that one station is less exposed to the wind than the other.

The monthly records of evaporation which are deposited in Engineering Societies Library, in New York, N Y., give all available information regarding the various factors, but it was obviously impossible to present the details in the yearly summaries published in the writer's paper. The monthly records also give the source of each record.

Another reason for apparent discrepancies in some instances probably may be charged to human fallibility, and lies in errors in the observed records themselves; but, undoubtedly, there are errors in the reduction factors used, as they probably do not apply strictly in every instance.

Even with the known limitations it was felt that the bringing together on as comparable a basis as possible (and that basis the one that the engineer needs in his use of evaporation records), all records known to the writer, was a worthwhile contribution to the subject of evaporation from the practical engineering standpoint.

Mr. Grunsky's criticism of the floating pan as a method of measuring evaporation is corroborated by the discrepant comparisons cited by the writer in his original paper. Two other comparisons have come to the writer's attention. In Turkestan, E. M. Oldekop, a Russian engineer, compared records of evaporation between floating pans and land pans, and came to the conclusion that a factor of 0.73 was required to reduce the records of the former to reservoir surface evaporation.[48] Near Paramaribo, Suriname (Dutch Guiana), Dutch engineers compared the evaporation between a circular tank of concrete, 5.25 ft in diameter and 2.5 ft deep, sunk in the ground and three concrete tanks which have a rectangular surface, 3.3 by 2.6 ft, suspended in the water at a distance of 2 miles from the ground tank, and found that the floating tanks gave results which were 89% of those of the ground tank. Assuming that the ground tank requires a coefficient of 0.95 to reduce it to reservoir surface evaporation the comparison indicates that the coefficient for the floating tanks is 1.06.[49] Table 17, Item 9(*a*) is a circular concrete pan, 6.3 ft in diameter and 2.95 ft deep, sunk in the ground, with the top 4 in. above the surface and a coefficient of 0.95. As far as the writer has been able to learn, practically no attempts have been made in foreign countries to compare evaporation records from pans with those of larger bodies of water, and Sleight's classic experiments at Denver, Colo., are still the nearest approach to it that has been attempted.

From what has been stated, it is not surprising that Mr. Randell found discrepancies in the records presented by the writer, and it is obviously impossible to reduce them to one standard of meteorological factors, as much as such a procedure might be desirable. Other commentators have called attention to variations in these factors within a comparatively short distance of the evaporation pans, thus further emphasizing the fact that they are not directly comparable in many instances. The various comments are most valuable in bringing out the fact that evaporation records, even when carefully taken, are subject to considerable error and cannot be accepted as exact.

---

[48] "The Evaporation from the Surface of the River Syr-Darya According to Observations at the Station Saporozskaya," *Journal of Irrigation No. 1,* 1924, Tashkent.

[49] *De Waterstaats Ingenieur.* May, 1924, No. 5, Batavia, Java.

It may be true, as suggested by Mr. Santos, that temperature, relative humidity, and wind velocity are not the only factors influencing evaporation, but in the vast majority of the existing records these are the only factors known and, in many instances, they are known only imperfectly.

Mr. Houk calls attention to the fact, recognized by the writer, that in arid regions, where large reservoirs are most likely to be constructed, relative humidity of the atmosphere adjacent to the water surface will be considerably higher than before such construction, with a corresponding decrease in evaporation. In humid regions, however, the effect on relative humidity will be much less marked. The writer cannot agree with Mr. Houk in thinking that the coefficient of 0.69 for the Yuma Citrus Station is much too high to show the actual evaporation under existing conditions. As Mr. Houk stated in a previous discussion,[50] the evaporation station known as Yuma Citrus Station is situated on a desert mesa where the (unmeasured) relative humidity must be very much less than that at the Yuma Date Orchard Station situated in an irrigated alfalfa field. The measured wind velocity is nearly twice as great at the Citrus Station as to the Date Orchard Station. Both these conditions are conducive to greater evaporation at the former station. However, if a reservoir were constructed at the former site the relative humidity would be increased and the evaporation decreased, although it appears to the writer that the greater wind velocity would still cause a higher rate of evaporation than in the more sheltered Date Orchard Station.

Evaporation Records from Foreign Countries.—Since transmitting the original paper, correspondence has been carried on with Government officials in every country where evaporation records might be available, and, as a result, nearly 200 foreign records have been obtained, together with records of temperature, wind velocity, and relative humidity, where these were available. These latter records may not be directly comparable in each instance. The records may be divided into three classes: (1) Records taken by means of equipment for which reduction factors to reservoir evaporation are fairly well known: (2) records from the Wild balance, an instrument widely used in foreign countries and for which some comparative results with standard equipment are available; and (3) records from Piche tubes.

The records in Class (1) have been reduced to reservoir evaporation, and the summaries are presented in Table 17. Those for the Wild balance (Class (2)) are presented in Table 18 as observed, but the Piche records (Class (3)), being taken under such widely varying conditions and appearing so discrepant among themselves, are not presented. The monthly records themselves have been deposited in the Engineering Societies Library.

The records of reservoir evaporation in Table 17 are taken by equipment described briefly in Table 19. The three concrete boxes at Tansa Lake in Bombay, India (Table 19, Item (24)), are set at three different levels and remain submerged after the end of the monsoon. They are exposed to the atmosphere in turn as the lake level recedes. At Bhatgar (Table 19, Item (26)), the iron tank is set on a stand in a circular concrete tank, 15 ft in

* For stations in Southern Hemisphere, period is October to March.

diameter and 7 ft deep. The concrete tank is set 2 ft in the ground. The evaporation records for this station are suspended during the monsoon, June to September, and for that period the evaporation has been estimated. At the Mettur Reservoir (Table 19, Item (27)), records are continuous throughout the year.

In Table 19, Item (29), a type of iron pan is described that rests on the bottom of a second iron pan. The latter is sunk in the ground with a 5-in. space between the sides of the two, which is filled with water. A similar arrangement is reported for Perth, West Australia, where the slate box (Table 19, Item (30)) is placed inside a concrete tank with a clearance of 5 in. on the sides and bottom.

The Wild balance consists essentially of a circular pan, 7 in. in diameter, resting on a balance. It is believed that the change in elevation of the pan itself, due to the lessening of the weight through evaporation, is indicated by a pointer on a curved scale.
